About This Book	xiii
Who Should Use This Book	xiii
Highlighting	xiii
ISO 9000	xiii
Related Publications	xiii
Trademarks	xiv
Chapter 1. Performance Concepts	1
How Fast is That Computer?	1
Understanding the Workload	1
Industry-Standard Benchmarks: A Risky Shortcut	2
Performance Objectives	2
Program Execution Dynamics	2
Hardware Hierarchy	3
Software Hierarchy	4
System Dynamics	6
Classes of Workload	6
Introducing the Performance-Tuning Process	7
Identifying the Workloads	8
Setting Objectives	8
Identifying Critical Resources	8
Minimizing Critical-Resource Requirements	9
Reflecting Priorities in Resource Allocation	10
Repeating the Tuning Steps	10
Applying Additional Resources	10
Performance Benchmarking	10
Related Information	12
Chapter 2. Resource Management Overview	15
Performance Overview of the CPU Scheduler	15
Thread Support	15
Processes and Threads	15
Process and Thread Priority	16
Scheduling Policy for Threads	18
Scheduler Run Queue	18
Scheduler CPU Time Slice	20
Mode Switching	20
Performance Overview of the Virtual Memory Manager (VMM)	21
Real-Memory Management	21
VMM Memory Load Control Facility	25
Allocation and Reclamation of Paging Space Slots	27
Performance Overview of Fixed-Disk Storage Management	28
Sequential-Access Read Ahead	30
Write Behind	31
Memory Mapped Files and Write Behind	31
Disk-I/O Pacing	31
Chapter 3. Introduction to Multiprocessing	33
Symmetrical Multiprocessor (SMP) Concepts and Architecture	33
Types of Multiprocessing	33
Symmetrical versus Asymmetrical Multiprocessors	35
Parallelizing an Application	36
Data Serialization	37

Types of Locks	37
Lock Granularity	38
Locking Overhead	39
Waiting for Locks	39
Cache Coherency	40
Processor Affinity and Binding	40
Memory and Bus Contention	41
SMP Performance Issues	41
Workload Concurrency	41
Throughput	41
Response Time	42
SMP Workloads	42
Workload Multiprocessability	42
Multiprocessor Throughput Scalability	43
Multiprocessor Response Time	44
SMP Thread Scheduling	45
Default Scheduler Processing of Migrated Workloads	45
Scheduling Algorithm Variables	46
Thread Tuning	47
Thread Environment Variables	47
Variables for Process-Wide Contention Scope	48
Thread Debug Options	49
Thread Tuning Summary	49
SMP Tools	50
The bindprocessor Command	50
The lockstat Command	52
The schedtune -s Command	55
Chapter 4. Planning and Implementing for Performance	57
Identifying the Components of the Workload	57
Documenting Performance Requirements	58
Estimating the Resource Requirements of the Workload	58
Measuring Workload Resources	60
Estimating Resources Required by a New Program	62
Transforming Program-Level Estimates to Workload Estimates	63
Designing and Implementing Efficient Programs	64
CPU-Limited Programs	65
Design and Coding for Effective Use of Caches	65
Registers and Pipeline	67
Cache and TLBs	67
Effective Use of Preprocessors and the Compilers	68
Levels of Optimization	68
Compiling for Specific Hardware Platforms (-qarch, -qtune)	69
C Options for string.h Subroutine Performance	69
C and C++ Coding Style for Best Performance	69
Compiler Execution Time	70
Memory-Limited Programs	70
Using Performance-Related Installation Guidelines	72
Operating System Preinstallation Guidelines	72
CPU Preinstallation Guidelines	72
Memory Preinstallation Guidelines	72
Disk Preinstallation Guidelines	73
Communications Preinstallation Guidelines	75
Chapter 5. System Monitoring and Initial Performance Diagnosis	77
The Case for Continuous Performance Monitoring	77

Using the vmstat, iostat, netstat, and sar Commands	77
Using the topas Monitor	79
Using the Performance Diagnostic Tool	82
Using the Performance Toolbox	82
Recording with the Performance Agent	83
Determining the Kind of Performance Problem Reported	83
A Particular Program Runs Slowly	83
Everything Runs Slowly at a Particular Time of Day	84
Everything Runs Slowly at Unpredictable Times	85
Everything That an Individual User Runs is Slow	85
A Number of LAN-Connected Systems Slow Down Simultaneously	85
Everything on a Particular Service or Device Slows Down at Times	86
Identifying the Performance-Limiting Resource	86
Determining the Limiting Factor for a Single Program	88
Determining Whether the Problem is Related to Disk or Memory	89
Managing Workload	91
Chapter 6. Monitoring and Tuning CPU Use	93
Monitoring CPU Use	93
The vmstat Command (CPU)	93
The iostat Command	96
The sar Command	96
The xmperv Program	100
Using the time Command to Measure CPU Use	100
time and timex Cautions	101
Identifying CPU-Intensive Programs	102
Using the ps Command	102
Using the acctcom Command	103
Using the tprof Program to Analyze Programs for CPU Use	104
A tprof Example	104
Offline Processing with the tprof Command	109
Using the pprof Command to Measure CPU usage of Kernel Threads	110
Detecting Instruction Emulation with the emstat Tool	112
Restructuring Executable Programs with the fdpr Program	113
Controlling Contention for the CPU	114
Controlling the Priority of User Processes	115
Displaying Process Priority with the ps Command	116
Modifying the Priority with the renice Command	116
Clarification of the nice and renice Command Syntax	117
Tuning the Thread-Priority-Value Calculation	117
Modifying the Scheduler Time Slice with the schedtune Command	120
CPU-Efficient User ID Administration (The mkpasswd Command)	120
Chapter 7. Monitoring and Tuning Memory Use	123
Determining How Much Memory Is Being Used	123
The vmstat Command (Memory)	123
The ps Command	126
The svmon Command	127
Correlating svmon and vmstat Outputs	134
Correlating svmon and ps Outputs	135
Calculating the Minimum Memory Requirement of a Program	136
Finding Memory-Leaking Programs	136
Assessing Memory Requirements Through the rmss Command	137
Two Styles of Using rmss	138
Interpreting rmss Results	141
Guidelines to Consider When Running the rmss Command	143

Tuning VMM Memory Load Control with the schedtune Command	143
Memory Load Control Tuning.	143
Tuning VMM Page Replacement with the vmtune Command	147
Choosing minfree and maxfree Settings.	147
Tuning Memory Pools	149
Tuning lrubucket to Reduce Memory Scanning Overhead	149
Choosing minperm and maxperm Settings	149
Placing a Hard Limit on Persistent File Cache with strict_maxperm.	150
Tuning Paging-Space Thresholds	150
Choosing npswarn and npskill Settings	151
Tuning the fork() Retry Interval Parameter with schedtune	151
Choosing a Page Space Allocation Method	152
Late Page Space Allocation	152
Early Page Space Allocation	152
Deferred Page Space Allocation	152
Choosing between LPSA and DPSA with the vmtune Command.	152
Looking at Paging Space and Virtual Memory	152
Using Shared Memory	153
Extended Shared Memory (EXTSHM)	153
Chapter 8. Monitoring and Tuning Disk I/O Use	155
Monitoring Disk I/O	155
Building a Pre-Tuning Baseline	156
Wait I/O Time Reporting	156
Assessing Disk Performance with the iostat Command	156
Assessing Disk Performance with the vmstat Command.	159
Assessing Disk Performance with the sar Command	160
Assessing Logical Volume Fragmentation with the lslv Command	161
Assessing Physical Placement of Data with the lslv Command	161
Assessing File Placement with the fileplace Command	162
Assessing Paging Space I/O with the vmstat Command.	163
Assessing Overall Disk I/O with the vmstat Command	164
Detailed I/O Analysis with the filemon Command	164
Summary for Monitoring Disk I/O	173
Changing File System Attributes that Affect Performance	173
File-System Fragment Size	174
Compression.	174
Changing Logical Volume Attributes That Affect Performance	175
Position on Physical Volume	175
Range of Physical Volumes	176
Maximum Number of Physical Volumes to Use for Allocation	177
Mirror Write Consistency	177
Allocate Each Logical Partition Copy on a Separate PV	178
Relocate the Logical Volume During Reorganization?.	178
Scheduling Policy for Reading/Writing Logical Partition Copies	178
Enable Write Verify	178
Striping Size	179
Physical Volume Considerations	179
Volume Group Recommendations	179
Performance Impacts of Mirroring rootvg	179
Reorganizing Logical Volumes	180
Recommendations for Best Performance	180
Recommendations for Highest Availability	181
Reorganizing File Systems	181
Reorganizing a File System	181
Defragmenting a File System.	182

Reorganizing JFS Log and Log Logical Volumes	182
Creating Log Logical Volumes	183
Tuning with vmtune	184
Sequential Read-Ahead.	184
VMM Write-Behind	185
Tuning File Syncs	186
Miscellaneous I/O Tuning Parameters	186
Using Disk-I/O Pacing	188
Example	188
Tuning Logical Volume Striping	189
Designing a Striped Logical Volume	190
Tuning for Striped Logical Volume I/O	191
Mirrored Striped Logical Volume Performance Implications	191
Tuning Asynchronous Disk I/O	192
Tuning Direct I/O	193
Performance of Direct I/O Reads	193
Performance of Direct I/O Writes	194
Performance Example	194
Summary	194
Using Raw Disk I/O	194
Using sync/fsync Calls	195
Setting SCSI-Adapter and Disk-Device Queue Limits	195
Non-IBM Disk Drive	196
Non-IBM Disk Array	196
Expanding the Configuration	196
Using RAID	197
RAID Levels and Their Performance Implications	197
Summary of RAID Levels	198
RAID Performance Summary.	199
Using SSA	199
Guidelines for Improving SSA Performance	199
Using Fast Write Cache	200
Chapter 9. Monitoring and Tuning Communications I/O Use	201
UDP and TCP/IP Performance Overview	201
Communication Subsystem Memory (mbuf) Management	203
Socket Layer.	203
Relative Level of Function in UDP and TCP	205
IP Layer	209
Demux Layer	210
LAN Adapters and Device Drivers	210
Analyzing Network Performance	212
The ping Command	212
The ftp Command	213
The netstat Command	214
The netpmn Command	224
The traceroute Command	232
The iptrace daemon, and the ipreport and ipfilter Commands	234
Adapter Statistics	236
The no Command	238
Tuning TCP and UDP Performance	238
Overall Recommendations.	238
Adapter Transmit and Receive Queue Tuning.	240
Tuning TCP Maximum Segment Size.	247
UDP Socket Buffer Tuning.	249

Misuses of NFS That Affect Performance	286
NFS Tuning Checklist	287
Chapter 11. Monitoring and Tuning Java	289
What is Java?	289
Why Java?	289
Java Performance Guidelines	289
Monitoring Java	290
Tuning Java	290

Chapter 12. Analyzing Performance with the Trace Facility	293
Understanding the Trace Facility	293
Implementation	294
Limiting the Amount of Trace Data Collected	294
Starting and Controlling Trace	294
Formatting Trace Data	295
Viewing Trace Data	295
Example of Trace Facility Use	295
Obtaining a Sample Trace File	295
Formatting the Sample Trace	295
Reading a Trace Report	296
Filtering of the Trace Report	297
Starting and Controlling Trace from the Command Line	297
Controlling Trace in Subcommand Mode	297
Controlling Trace by Commands	297
Starting and Controlling Trace from a Program	298
Controlling Trace with Trace Subroutine Calls	298
Controlling Trace with ioctl() Calls	298
Using the trcrpt Command to Format a Report	299
Formatting a Report on the Same System	300
Formatting a Report on a Different System	300
Formatting a Report from trace -C Output	300
Adding New Trace Events	301
Possible Forms of a Trace Event Record	301
Trace Channels	302
Macros for Recording Trace Events	302
Use of Event IDs	302
Examples of Coding and Formatting Events	303
Syntax for Stanzas in the Trace Format File	304
Chapter 13. Using Performance Diagnostic Tool (PDT)	305
Structure of PDT	305
Scope of PDT Analysis	306
Analyzing the PDT Report	307
Header	307
Alerts	308
Upward and Downward Trends	308

About This Book

This book provides information on concepts, tools, and techniques for assessing and tuning the performance of systems. Topics covered include efficient system and application design and implementation, as well as post-implementation tuning of CPU use, memory use, disk I/O, and communications I/O. Most of the tuning recommendations were developed or validated on AIX Version 4.

Who Should Use This Book

This book is intended for application programmers, customer engineers, experienced end users, enterprise system administrators, experienced system administrators, system engineers, and system programmers concerned with performance tuning of operating systems. You should be familiar with the operating system environment. Introductory sections are included to assist those who are less experienced and to acquaint experienced users with performance-tuning terminology.

Highlighting

The following highlighting conventions are used in this book:

Bold	Identifies commands, subroutines, keywords, files, structures, directories, and other items whose names are predefined by the system. Also identifies graphical objects such as buttons, labels, and icons that the user selects.
<i>Italics</i>	Identifies parameters whose actual names or values are to be supplied by the user.
Monospace	Identifies examples of specific data values, examples of text similar to what you might see displayed, examples of portions of program code similar to what you might write as a programmer, messages from the system, or information you should actually type.

ISO 9000

ISO 9000 registered quality systems were used in the development and manufacturing of this product.

Chapter 1. Performance Concepts

Everyone who uses a computer has an opinion about its performance. Unfortunately, those opinions are often based on oversimplified ideas about the dynamics of program execution. Uninformed intuition can lead to expensive and inaccurate guesses about the capacity of a system and the solutions to the perceived performance problems.

This chapter describes the dynamics of program execution and provides a conceptual framework for evaluating system performance. It contains the following major sections:

- How Fast is That Computer?
- Understanding the Workload
- Program Execution Dynamics
- System Dynamics
- Introducing the Performance-Tuning Process
- Performance Benchmarking
- Related Information

How Fast is That Computer?

Using words like *speed* and *fast* to describe contemporary computers, while accepted by precedent, is extreme oversimplification. There was a time when a programmer could read a program, calculate the sum of the instruction times, and confidently predict how long it would take the computer to run that program. Thousands of programmers and engineers have spent the last 30 years making such straightforward calculations impossible, or at least meaningless.

Today's computers are more powerful than their predecessors, not just because they use integrated circuits instead of vacuum tubes and have far shorter cycle times, but because of innumerable hardware and software architectural inventions. Each advance in integrated-circuit density brings an advance in computer performance, not just because it allows the same logic to work in a smaller space with a faster system clock, but because it gives engineers more space in which to implement ideas. In short, computers have gained capacity by becoming more complex as well as quicker.

The complexity of modern computers and their operating systems is matched by the complexity of the environment in which they operate. In addition to running individual programs, today's computer deals with varying numbers of unpredictably timed interrupts from I/O and communications devices. To the extent that the engineers' ideas were based on an assumption of a single program running in a standalone machine, they may be partly defeated by the randomness of the real world. To the extent that those ideas were intended to deal with randomness, they may win back some of the loss. The wins and losses change from program to program and from moment to moment.

The result of all these hardware and software wins and losses is the performance of the system. The speed of the system is the rate at which it can handle a specific sequence of demands. If the demands mesh well with the system's hardware and software architectures, we can say, "The system runs this workload fast." We cannot say, "The system is fast," or at least we should not.

Understanding the Workload

An accurate and complete definition of the system's workload is critical to predicting or understanding its performance. A difference in workload can cause far more variation in the measured performance of a system than differences in CPU clock speed or random access memory (RAM) size. The workload definition must include not only the type and rate of requests to the system, but also the exact software packages and in-house application programs to be executed.

Whenever possible, observe the current users of existing applications to get authentic, real-world measurements of the rates at which users interact with their workstations or terminals.

Make sure that you include the work that your system is doing "under the covers." For example, if your system contains file systems that are NFS-mounted and frequently accessed by other systems, handling those accesses is probably a significant fraction of the overall workload, even though your system is not officially a server.

Industry-Standard Benchmarks: A Risky Shortcut

A *benchmark* is a workload that has been standardized to allow comparisons among dissimilar systems. Any benchmark that has been in existence long enough to become industry-standard has been studied exhaustively by systems developers. Operating systems, compilers, and in some cases hardware, have been tuned to run the benchmark with lightning speed.

Unfortunately, few real workloads duplicate the exact algorithms and environment of a benchmark. Even those industry-standard benchmarks that were originally derived from real applications might have been simplified and homogenized to make them portable to a wide variety of hardware platforms. The environment in which they run has been constrained in the interests of reproducible measurements.

Any reasoning similar to "System A is rated at 50 percent more MegaThings than System B, so System A should run my program 50 percent faster than System B" might be a tempting shortcut, but may be inaccurate. There is no benchmark with such universal applicability. The only valid use for industry-standard benchmarks is to narrow the field of candidate systems that will be subjected to a serious evaluation. There is no substitute for developing a clear understanding of your workload and its performance in systems under consideration.

Performance Objectives

After defining the workload that the system will have to process, you can choose performance criteria and set performance objectives based on those criteria. The main overall performance criteria of computer systems are response time and throughput.

Response time is the elapsed time between when a request is submitted and when the response from that request is returned. Examples include how long a database query takes, or how long it takes to echo characters to the terminal, or how long it takes to access a Web page.

Throughput is a measure of the amount of work over a period of time. In other words, it is the number of workload operations that can be accomplished per unit of time. Examples include database transactions per minute, kilobytes of a file transferred per second, kilobytes of a file read or written per second, or Web server hits per minute.

The relationship between these metrics is complex. In some cases, you might have to trade off one against the other. In other situations, a single change can improve both. Sometimes you can have higher throughput at the cost of response time or better response time at the cost of throughput. Acceptable performance is based on reasonable throughput combined with reasonable response time.

In planning for or tuning any system, make sure that you have clear objectives for both response time and throughput when processing the specified workload. Otherwise, you risk spending analysis time and resource dollars improving an aspect of system performance that is of secondary importance.

Program Execution Dynamics

Normally, an application programmer thinks of the running program as an uninterrupted sequence of instructions that perform a specified function. Great amounts of inventiveness and effort have been expended on the operating system and hardware to ensure that programmers are not distracted from this idealized view by irrelevant space, speed, and multiprogramming or multiprocessing considerations. If the

programmer is seduced by this comfortable illusion, the resulting program might be unnecessarily expensive to run and might not meet its performance objectives.

To examine clearly the performance characteristics of a workload, a dynamic, rather than a static, model of program execution is needed, as shown in the following figure.

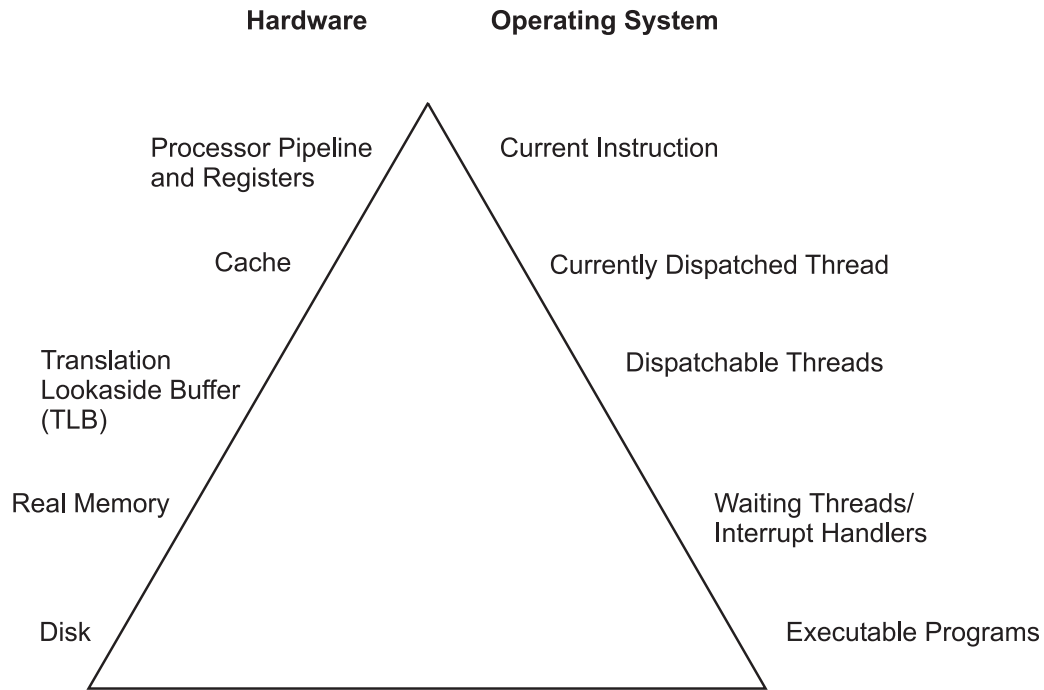

Figure 1. Program Execution Hierarchy. The figure is a triangle on its base. The left side represents hardware entities that are matched to the appropriate operating system entity on the right side. A program must go from the lowest level of being stored on disk, to the highest level being the processor running program instructions. For instance, from bottom to top, the disk hardware entity holds executable programs; real memory holds waiting operating system threads and interrupt handlers; the translation lookaside buffer holds detachable threads; cache contains the currently dispatched thread and the processor pipeline and registers contain the current instruction.

To run, a program must make its way up both the hardware and operating-system hierarchies, more or less in parallel. Each element in the hardware hierarchy is scarcer and more expensive than the element below it. Not only does the program have to contend with other programs for each resource, the transition from one level to the next takes time. To understand the dynamics of program execution, you need a basic understanding of each of the levels in the hierarchy.

Hardware Hierarchy

Usually, the time required to move from one hardware level to another consists primarily of the latency of the lower level (the time from the issuing of a request to the receipt of the first data).

Fixed Disks

The slowest operation for a running program (other than waiting for a human keystroke) on a standalone system is obtaining code or data from a disk, for the following reasons:

- The disk controller must be directed to access the specified blocks (queuing delay).
- The disk arm must seek to the correct cylinder (seek latency).
- The read/write heads must wait until the correct block rotates under them (rotational latency).
- The data must be transmitted to the controller (transmission time) and then conveyed to the application program (interrupt-handling time).

Disk operations can have many causes besides explicit read or write requests in the program. System-tuning activities frequently prove to be hunts for unnecessary disk I/O.

Real Memory

Real Memory, often referred to as RAM, is fast compared to disk, but much more expensive per byte. Operating systems try to keep in RAM the code and data that are currently in use, spilling any excess onto disk (or never bringing them into RAM in the first place).

RAM is not necessarily fast compared to the processor. Typically a RAM latency of dozens of processor cycles occurs between the time the hardware recognizes the need for a RAM access and the time the data or instruction is available to the processor.

If the access is to a page of virtual memory that has been spilled to disk (or has not been brought in yet), a page fault occurs, and the execution of the program is suspended until the page has been read in from disk.

Translation Lookaside Buffer (TLB)

One of the ways programmers are insulated from the physical limitations of the system is the implementation of virtual memory. The programmer designs and codes the program as though the memory were very large, and the system takes responsibility for translating the program's virtual addresses for instructions and data into the real addresses that are needed to get the instructions and data from RAM. Because this address-translation process can be time-consuming, the system keeps the real addresses of recently accessed virtual-memory pages in a cache called the translation lookaside buffer (TLB).

As long as the running program continues to access a small set of program and data pages, the full virtual-to-real page-address translation does not need to be redone for each RAM access. When the program tries to access a virtual-memory page that does not have a TLB entry (a TLB miss), dozens of processor cycles (the TLB-miss latency) are usually required to perform the address translation.

Caches

To minimize the number of times the program has to experience the RAM latency, systems incorporate caches for instructions and data. If the required instruction or data is already in the cache (a cache hit), it is available to the processor on the next cycle (that is, no delay occurs). Otherwise (a cache miss), the RAM latency occurs.

In some systems, there are two or three levels of cache, usually called L1, L2, and L3. If a particular storage reference results in an L1 miss, then L2 is checked. If L2 generates a miss, then the reference goes to the next level, either L3 if present or RAM.

Cache sizes and structures vary by model, but the principles of using them efficiently are identical.

Pipeline and Registers

A pipelined, superscalar architecture makes possible, under certain circumstances, the simultaneous processing of multiple instructions. Large sets of general-purpose registers and floating-point registers make it possible to keep considerable amounts of the program's data in registers, rather than continually storing and reloading.

The optimizing compilers are designed to take maximum advantage of these capabilities. The compilers' optimization functions should always be used when generating production programs, however small the programs are. The *Optimization and Tuning Guide for XL Fortran, XL C and XL C++* describes how programs can be tuned for maximum performance.

Software Hierarchy

To run, a program must also progress through a series of steps in the software hierarchy.

Executable Programs

When a user requests a program to run, the operating system performs a number of operations to transform the executable program on disk to a running program. First, the directories in the user's current **PATH** environment variable must be scanned to find the correct copy of the program. Then, the system loader (not to be confused with the **ld** command, which is the binder) must resolve any external references from the program to shared libraries.

To represent the user's request, the operating system creates a process, which is a set of resources, such as a private virtual address segment, required by any running program.

In AIX Version 4, the operating system also automatically creates a single thread within that process. A *thread* is the current execution state of a single instance of a program. In AIX Version 4, access to the processor and other resources is allocated on a thread basis, rather than a process basis. Multiple threads can be created within a process by the application program. Those threads share the resources owned by the process within which they are running.

Finally, the system branches to the entry point of the program. If the program page that contains the entry point is not already in memory (as it might be if the program had been recently compiled, executed, or copied), the resulting page-fault interrupt causes the page to be read from its backing storage.

Interrupt Handlers

The mechanism for notifying the operating system that an external event has taken place is to interrupt the currently running thread and transfer control to an interrupt handler. Before the interrupt handler can run, enough of the hardware state must be saved to ensure that the system can restore the context of the thread after interrupt handling is complete. Newly invoked interrupt handlers experience all of the delays of moving up the hardware hierarchy (except page faults). Unless the interrupt handler was run very recently (or the intervening programs were very economical), it is unlikely that any of its code or data remains in the TLBs or the caches.

When the interrupted thread is dispatched again, its execution context (such as register contents) is logically restored, so that it functions correctly. However, the contents of the TLBs and caches must be reconstructed on the basis of the program's subsequent demands. Thus, both the interrupt handler and the interrupted thread can experience significant cache-miss and TLB-miss delays as a result of the interrupt.

Waiting Threads

Whenever an executing program makes a request that cannot be satisfied immediately, such as an I/O operation (either explicit or as the result of a page fault), that thread is put in a wait state until the request is complete. Normally, this results in another set of TLB and cache latencies, in addition to the time required for the request itself.

Dispatchable Threads

When a thread is dispatchable, but not actually running, it is accomplishing nothing useful. Worse, other threads that are running may cause the thread's cache lines to be reused and real memory pages to be reclaimed, resulting in even more delays when the thread is finally dispatched.

Currently Dispatched Threads

The scheduler chooses the thread that has the strongest claim to the use of the processor. The considerations that affect that choice are discussed in Performance Overview of the CPU Scheduler. When the thread is dispatched, the logical state of the processor is restored to the state that was in effect when the thread was interrupted.

Current Instructions

Most of the machine instructions are capable of executing in a single processor cycle, if no TLB or cache miss occurs. In contrast, if a program branches rapidly to different areas of the program and accesses data from a large number of different areas, causing high TLB and cache-miss rates, the average number of processor cycles per instruction (CPI) executed might be much greater than one. The program is said to exhibit poor locality of reference. It might be using the minimum number of instructions necessary to do its

job, but consuming an unnecessarily large number of cycles. In part because of this poor correlation between number of instructions and number of cycles, reviewing a program listing to calculate path length no longer yields a time value directly. While a shorter path is usually faster than a longer path, the speed ratio can be very different from the path-length ratio.

The compilers rearrange code in sophisticated ways to minimize the number of cycles required for the execution of the program. The programmer seeking maximum performance must be primarily concerned with ensuring that the compiler has all the information necessary to optimize effectively, rather than trying to second-guess the compiler's optimization techniques (see Effective Use of Preprocessors and the Compilers). The real measure of optimization effectiveness is the performance of an authentic workload.

System Dynamics

It is not enough to create the most efficient possible individual programs. In many cases, the actual programs being run were created outside of the control of the person who is responsible for meeting the organization's performance objectives. Further, most of the levels of the hierarchy described in Program Execution Dynamics are managed by one or more parts of the operating system. In any case, after the application programs have been acquired, or implemented as efficiently as possible, further improvement in the overall performance of the system becomes a matter of system tuning. The main components that are subject to system-level tuning are:

Communications I/O

Depending on the type of workload and the type of communications link, it might be necessary to tune one or more of the communications device drivers, TCP/IP, or NFS.

Fixed Disk

The Logical Volume Manager (LVM) controls the placement of file systems and paging spaces on the disk, which can significantly affect the amount of seek latency the system experiences. The disk device drivers control the order in which I/O requests are acted on.

Real Memory

The Virtual Memory Manager (VMM) controls the pool of free real-memory frames and determines when and from whom to steal frames to replenish the pool.

Running Thread

The scheduler determines which dispatchable entity should next receive control. In AIX Version 4, the dispatchable entity changes from a process to a thread. See Thread Support.

Classes of Workload

Workloads tend to fall naturally into a small number of classes. The types listed below are sometimes used to categorize systems. However, because a single system is often called upon to process multiple classes, workload seems more apt in the context of performance.

Multiuser

A workload that consists of a number of users submitting work through individual terminals. Typically, the performance objectives of such a workload are either to maximize system throughput while preserving a specified worst-case response time or to obtain the best possible response time for a fairly constant workload.

Server

A workload that consists of requests from other systems. For example, a file-server workload is mostly disk read/write requests. In essence, it is the disk-I/O component of a multiuser workload (plus NFS or other I/O activity), so the same objective of maximum throughput within a given response-time limit applies. Other server workloads consist of compute-intensive programs, database transactions, printer jobs, and so on.

Workstation

A workload that consists of a single user submitting work through the native keyboard and

receiving results on the native display of the system. Typically, the highest-priority performance objective of such a workload is minimum response time to the user's requests.

When a single system is processing workloads of more than one type, a clear understanding must exist between the users and the performance analyst as to the relative priorities of the possibly conflicting performance objectives of the different workloads.

Introducing the Performance-Tuning Process

Performance tuning is primarily a matter of resource management and correct system-parameter setting. Tuning the workload and the system for efficient resource use consists of the following steps:

1. Identifying the workloads on the system
2. Setting objectives:
 - a. Determining how the results will be measured
 - b. Quantifying and prioritizing the objectives
3. Identifying the critical resources that limit the system's performance
4. Minimizing the workload's critical-resource requirements:
 - a. Using the most appropriate resource, if there is a choice
 - b. Reducing the critical-resource requirements of individual programs or system functions
 - c. Structuring for parallel resource use
5. Modifying the allocation of resources to reflect priorities
 - a. Changing the priority or resource limits of individual programs
 - b. Changing the settings of system resource-management parameters
6. Repeating steps 3 through 5 until objectives are met (or resources are saturated)
7. Applying additional resources, if necessary

There are appropriate tools for each phase of system performance management (see Appendix A. Monitoring and Tuning Commands and Subroutines). Some of the tools are available from IBM; others are the products of third parties. The following figure illustrates the phases of performance management in a simple LAN environment.

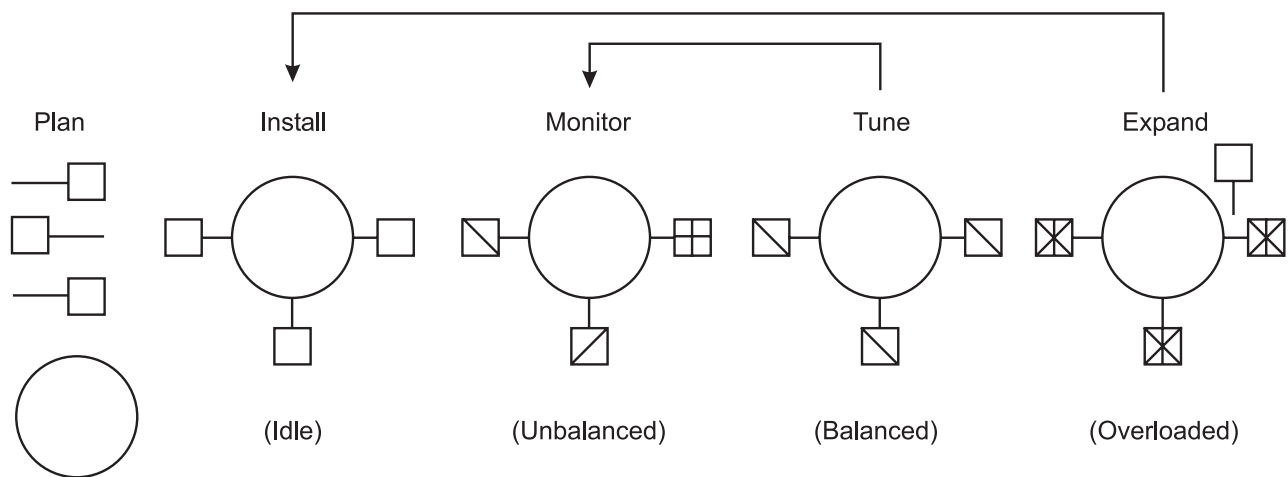

Figure 2. Performance Phases. The figure uses five weighted circles to illustrate the steps of performance tuning a system; plan, install, monitor, tune, and expand. Each circle represents the system in various states of performance; idle, unbalanced, balanced, and overloaded. Essentially, you expand a system that is overloaded, tune a system until it is balanced, monitor an unbalanced system and install for more resources when an expansion is necessary.

Identifying the Workloads

It is essential that all of the work performed by the system be identified. Especially in LAN-connected systems, a complex set of cross-mounted file systems can easily develop with only informal agreement among the users of the systems. These file systems must be identified and taken into account as part of any tuning activity.

With multiuser workloads, the analyst must quantify both the typical and peak request rates. It is also important to be realistic about the proportion of the time that a user is actually interacting with the terminal.

An important element of this identification stage is determining whether the measurement and tuning activity has to be done on the production system or can be accomplished on another system (or off-shift) with a simulated version of the actual workload. The analyst must weigh the greater authenticity of results from a production environment against the flexibility of the nonproduction environment, where the analyst can perform experiments that risk performance degradation or worse.

Setting Objectives

Although you can set objectives in terms of measurable quantities, the actual desired result is often subjective, such as satisfactory response time. Further, the analyst must resist the temptation to tune what is measurable rather than what is important. If no system-provided measurement corresponds to the desired improvement, that measurement must be devised.

The most valuable aspect of quantifying the objectives is not selecting numbers to be achieved, but making a public decision about the relative importance of (usually) multiple objectives. Unless these priorities are set in advance, and understood by everyone concerned, the analyst cannot make trade-off decisions without incessant consultation. The analyst is also apt to be surprised by the reaction of users or management to aspects of performance that have been ignored. If the support and use of the system crosses organizational boundaries, you might need a written service-level agreement between the providers and the users to ensure that there is a clear common understanding of the performance objectives and priorities.

Identifying Critical Resources

In general, the performance of a given workload is determined by the availability and speed of one or two critical system resources. The analyst must identify those resources correctly or risk falling into an endless trial-and-error operation.

Systems have both real and logical resources. Critical real resources are generally easier to identify, because more system performance tools are available to assess the utilization of real resources. The real resources that most often affect performance are as follows:

- CPU cycles
- Memory
- I/O bus
- Various adapters
- Disk arms
- Disk space
- Network access

Logical resources are less readily identified. Logical resources are generally programming abstractions that partition real resources. The partitioning is done to share and manage the real resource.

Some examples of real resources and the logical resources built on them are as follows:

CPU

- Processor time slice

Memory

- Page frames
- Stacks
- Buffers
- Queues
- Tables
- Locks and semaphores

Disk Space

- Logical volumes
- File systems
- Files
- Partitions

Network Access

- Sessions
- Packets
- Channels

It is important to be aware of logical resources as well as real resources. Threads can be blocked by a lack of logical resources just as for a lack of real resources, and expanding the underlying real resource does not necessarily ensure that additional logical resources will be created. For example, consider the NFS block I/O daemon (**biobd**, see Tuning for NFS Performance). A **biobd** daemon on the client is required to handle each pending NFS remote I/O request. The number of **biobd** daemons therefore limits the number of NFS I/O operations that can be in progress simultaneously. When a shortage of **biobd** daemons exists, system instrumentation may indicate that the CPU and communications links are used only slightly. You may have the false impression that your system is underused (and slow), when in fact you have a shortage of **biobd** daemons that is constraining the rest of the resources. A **biobd** daemon uses processor cycles and memory, but you cannot fix this problem simply by adding real memory or converting to a faster CPU. The solution is to create more of the logical resource (**biobd** daemons).

Logical resources and bottlenecks can be created inadvertently during application development. A method of passing data or controlling a device may, in effect, create a logical resource. When such resources are created by accident, there are generally no tools to monitor their use and no interface to control their allocation. Their existence may not be appreciated until a specific performance problem highlights their importance.

Minimizing Critical-Resource Requirements

Consider minimizing the workload's critical-resource requirements at three levels, as discussed below.

Using the Appropriate Resource

The decision to use one resource over another should be done consciously and with specific goals in mind. An example of a resource choice during application development would be a trade-off of increased memory consumption for reduced CPU consumption. A common system configuration decision that demonstrates resource choice is whether to place files locally on an individual workstation or remotely on a server.

Reducing the Requirement for the Critical Resource

For locally developed applications, the programs can be reviewed for ways to perform the same function more efficiently or to remove unnecessary function. At a system-management level, low-priority workloads that are contending for the critical resource can be moved to other systems, run at other times, or controlled with the Workload Manager.

Structuring for Parallel Use of Resources

Because workloads require multiple system resources to run, take advantage of the fact that the resources are separate and can be consumed in parallel. For example, the operating system read-ahead algorithm detects the fact that a program is accessing a file sequentially and schedules additional sequential reads to be done in parallel with the application's processing of the previous data. Parallelism applies to system management as well. For example, if an application accesses two or more files at the same time, adding an additional disk drive might improve the disk-I/O rate if the files that are accessed at the same time are placed on different drives.

Reflecting Priorities in Resource Allocation

The operating system provides a number of ways to prioritize activities. Some, such as disk pacing, are set at the system level. Others, such as process priority, can be set by individual users to reflect the importance they attach to a specific task.

Repeating the Tuning Steps

A truism of performance analysis is that there is always a next bottleneck. Reducing the use of one resource means that another resource limits throughput or response time. Suppose, for example, we have a system in which the utilization levels are as follows:

CPU: 90% Disk: 70% Memory 60%

This workload is CPU-bound. If we successfully tune the workload so that the CPU load is reduced from 90 to 45 percent, we might expect a two-fold improvement in performance. Unfortunately, the workload is now I/O-limited, with utilizations of approximately the following:

CPU: 45% Disk: 90% Memory 60%

The improved CPU utilization allows the programs to submit disk requests sooner, but then we hit the limit imposed by the disk drive's capacity. The performance improvement is perhaps 30 percent instead of the 100 percent we had envisioned.

There is always a new critical resource. The important question is whether we have met the performance objectives with the resources at hand.

Applying Additional Resources

If, after all of the preceding approaches have been exhausted, the performance of the system still does not meet its objectives, the critical resource must be enhanced or expanded. If the critical resource is logical and the underlying real resource is adequate, the logical resource can be expanded at no additional cost. If the critical resource is real, the analyst must investigate some additional questions:

- How much must the critical resource be enhanced or expanded so that it ceases to be a bottleneck?
- Will the performance of the system then meet its objectives, or will another resource become saturated first?
- If there will be a succession of critical resources, is it more cost-effective to enhance or expand all of them, or to divide the current workload with another system?

Performance Benchmarking

When we attempt to compare the performance of a given piece of software in different environments, we are subject to a number of possible errors, some technical, some conceptual. This section contains mostly cautionary information. Other sections of this book discuss the various ways in which elapsed and process-specific times can be measured.

When we measure the elapsed (wall-clock) time required to process a system call, we get a number that consists of the following:

- The actual time during which the instructions to perform the service were executing
- Varying amounts of time during which the processor was stalled while waiting for instructions or data from memory (that is, the cost of cache and TLB misses)
- The time required to access the clock at the beginning and end of the call
- Time consumed by periodic events, such as system timer interrupts
- Time consumed by more or less random events, such as I/O interrupts

To avoid reporting an inaccurate number, we normally measure the workload a number of times. Because all of the extraneous factors add to the actual processing time, the typical set of measurements has a curve of the form shown in the following illustration.

Figure 3. Curve for Typical Set of Measurement.

The extreme low end may represent a low-probability optimum caching situation or may be a rounding effect.

A regularly recurring extraneous event might give the curve a bimodal form (two maxima), as shown in the following illustration.

Figure 4. Bimodal Curve

One or two time-consuming interrupts might skew the curve even further, as shown in the following illustration:

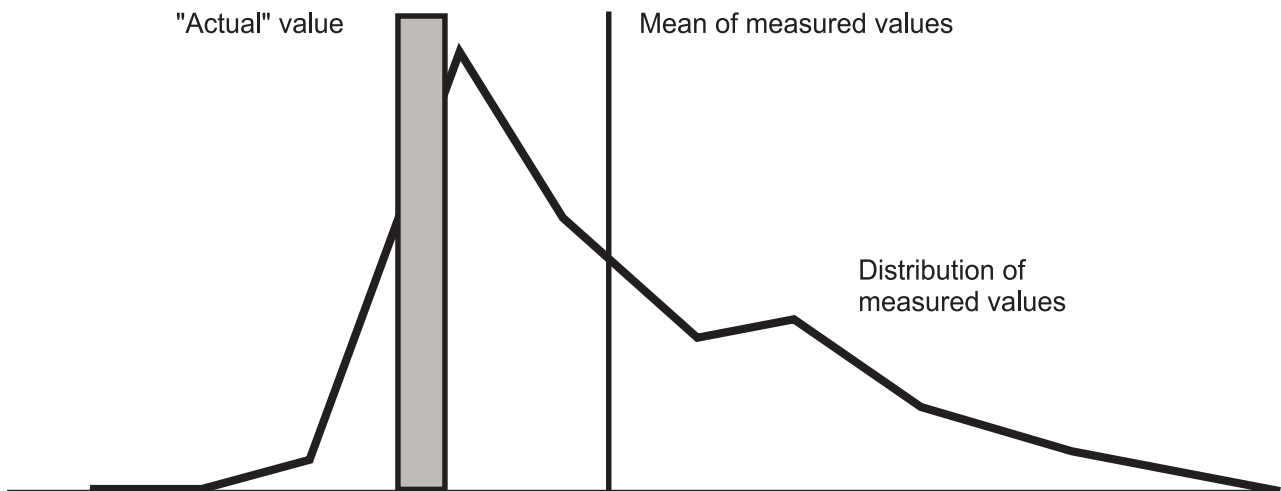

Figure 5. Skewed Curve

The distribution of the measurements about the actual value is not random, and the classic tests of inferential statistics can be applied only with great caution. Also, depending on the purpose of the measurement, it may be that neither the mean nor the actual value is an appropriate characterization of performance.

Chapter 2. Resource Management Overview

This chapter describes the components of the operating system that manage the resources that have the most effect on system performance, and the ways in which these components can be tuned. This chapter contains the following major sections:

- Performance Overview of the CPU Scheduler.
- Performance Overview of the Virtual Memory Manager (VMM).
- Performance Overview of Fixed-Disk Storage Management.

Specific tuning recommendations appear in the following:

- Chapter 6. Monitoring and Tuning CPU Use.
- Chapter 7. Monitoring and Tuning Memory Use.
- Chapter 8. Monitoring and Tuning Disk I/O Use.
- Chapter 9. Monitoring and Tuning Communications I/O Use.
- Chapter 10. Monitoring and Tuning NFS Use.

Performance Overview of the CPU Scheduler

The CPU scheduler has been modified in version 4 of the operating system to include thread support. Conceptually, the scheduling algorithm and priority scheme have not changed, but the addition of thread support required many detail-level changes. Although the net behavioral change for unchanged applications running on uniprocessors might be small, anyone concerned with performance tuning should understand the changes and the opportunities.

Thread Support

A *thread* can be thought of as a low-overhead process. It is a dispatchable entity that requires fewer resources to create than a process. The fundamental dispatchable entity of the AIX Version 4 scheduler is the thread.

Processes have not ceased to exist. In fact, workloads migrated directly from earlier releases of the operating system continue to create and manage processes. Each new process is created with a single thread that has its parent process priority and contends for the CPU with the threads of other processes. The process owns the resources used in execution; the thread owns only its current state.

When new or modified applications take advantage of the operating system's thread support to create additional threads, those threads are created within the context of the process. They share the process's private segment and other resources.

A user thread within a process has a specified *contention scope*. If the contention scope is *global*, the thread contends for CPU time with all other threads in the system. The thread that is created when a process is created has global contention scope. If the contention scope is *local*, the thread contends with the other threads within the process to be the recipient of the process's share of CPU time.

The algorithm for determining which thread should be run next is called a *scheduling policy*.

Processes and Threads

A process is an activity within the system that is started by a command, a shell program, or another process.

Process properties are as follows:

- pid

- pgid
- uid
- gid
- environment
- cwd
- file descriptors
- signal actions
- process statistics
- nice

These properties are defined in `/usr/include/sys/proc.h`.

Thread properties are as follows:

- stack
- scheduling policy
- scheduling priority
- pending signals
- blocked signals
- thread-specific data

These thread properties are defined in `/usr/include/sys/thread.h`.

Each process is made up of one or more threads. A thread is a single sequential flow of control. Multiple threads of control allow an application to overlap operations, such as reading from a terminal and writing to a file.

Multiple threads of control also allow an application to service requests from multiple users at the same time. Threads provide these capabilities without the added overhead of multiple processes such as those created through the `fork()` system call.

AIX 4.3.1 introduced a fast fork routine called `f_fork()`. This routine is very useful for multithreaded applications that will call the `exec()` subroutine immediately after they would have called the `fork()` subroutine. The `fork()` subroutine is slower because it has to call fork handlers to acquire all the library locks before actually forking and letting the child run all child handlers to initialize all the locks. The `f_fork()` subroutine bypasses these handlers and calls the `kfork()` system call directly. Web servers are a good example of an application that can use the `f_fork()` subroutine.

Process and Thread Priority

The priority management tools manipulate process priority. In AIX Version 4, process priority is simply a precursor to thread priority. When the `fork()` subroutine is called, a process and a thread to run in it are created. The thread has the priority that would have been attributed to the process.

The kernel maintains a *priority value* (sometimes termed the *scheduling priority*) for each thread. The priority value is a positive integer and varies inversely with the importance of the associated thread. That is, a smaller priority value indicates a more important thread. When the scheduler is looking for a thread to dispatch, it chooses the dispatchable thread with the smallest priority value.

A thread can be fixed-priority or nonfixed priority. The priority value of a fixed-priority thread is constant, while the priority value of a nonfixed-priority thread varies based on the minimum priority level for user threads (a constant 40), the thread's nice value (20 by default, optionally set by the `nice` or `renice` command), and its CPU-usage penalty.

The priority of a thread can be fixed at a certain value, which can have a priority value less than 40, if their priority is set (fixed) through the **setpri()** subroutine. These threads are immune to the scheduler recalculation algorithms. If their priority values are fixed to be less than 40, these threads will run and complete before any user threads can run. For example, a thread with a fixed value of 10 will run before a thread with a fixed value of 15.

Users can apply the **nice** command to make a thread's nonfixed priority less favorable. The system manager can apply a negative nice value to a thread, thus giving it a better priority.

The following illustration shows some of the ways in which the priority value can change.

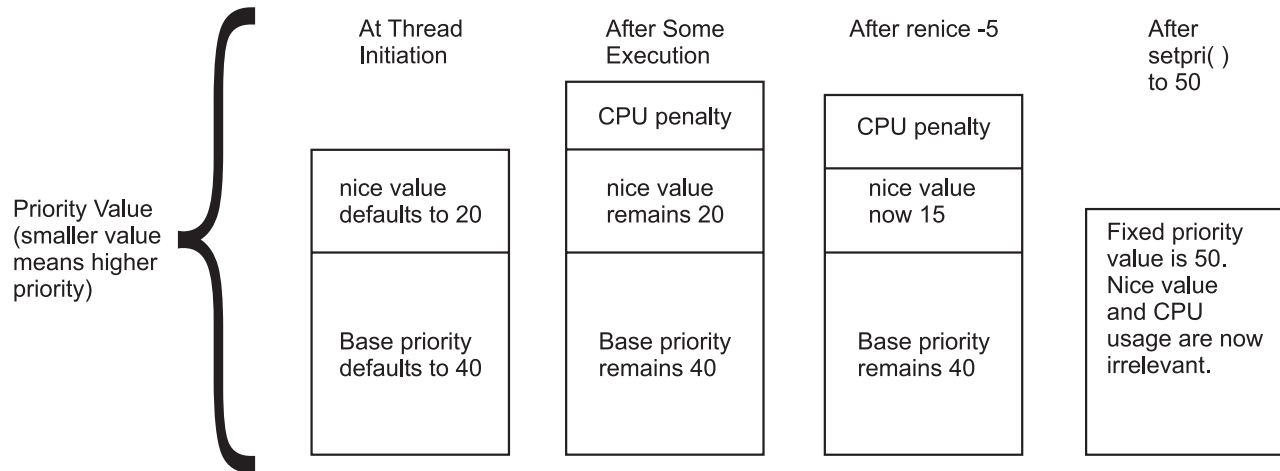

Figure 6. How the Priority Value is Determined. The illustration shows how the scheduling priority value of a thread can change during execution or after applying the nice command. The smaller the priority value, the higher the thread priority. At initiation, the nice value defaults to 20 and the base priority defaults to 40. After some execution and a CPU penalty, the nice value remains 20 and the base priority remains 40. After running the renice -5 command and with the same CPU usage as before, the nice value is now 15 and the base priority remains 40. After issuing the setpri() subroutine with a value of 50, fixed priority is now 50 and the nice value and CPU usage is irrelevant.

The nice value of a thread is set when the thread is created and is constant over the life of the thread, unless explicitly changed by the user through the **renice** command or the **setpri()**, **setpriority()**, **thread_setsched()**, or **nice()** system calls.

The CPU penalty is an integer that is calculated from the recent CPU usage of a thread. The recent CPU usage increases by approximately 1 each time the thread is in control of the CPU at the end of a 10 ms clock tick, up to a maximum value of 120. The actual priority penalty per tick increases with the **nice** value. Once per second, the recent CPU usage values for all threads are recalculated.

The result is the following:

- The priority of a nonfixed-priority thread becomes less favorable as its recent CPU usage increases and vice versa. This implies that, on average, the more time slices a thread has been allocated recently, the less likely it is that the thread will be allocated the next time slice.
- The priority of a nonfixed-priority thread becomes less favorable as its nice value increases, and vice versa.

You can use the **ps** command to display the priority value, nice value, and short-term CPU-usage values for a process.

See Controlling Contention for the CPU for a more detailed discussion on using the **nice** and **renice** commands.

See Tuning the Thread-Priority-Value Calculation, for the details of the calculation of the CPU penalty and the decay of the recent CPU usage values.

Scheduling Policy for Threads

In AIX Version 4, the five possible values for thread scheduling policy are as follows:

SCHED_FIFO

After a thread with this policy is scheduled, it runs to completion unless it is blocked, it voluntarily yields control of the CPU, or a higher-priority thread becomes dispatchable. Only fixed-priority threads can have a SCHED_FIFO scheduling policy.

SCHED_RR

When a SCHED_RR thread has control at the end of the time slice, it moves to the tail of the queue of dispatchable threads of its priority. Only fixed-priority threads can have a SCHED_RR scheduling policy.

SCHED_OTHER

This policy is defined by POSIX Standard 1003.4a as implementation-defined. The recalculation of the running thread's priority value at each clock interrupt means that a thread may lose control because its priority value has risen above that of another dispatchable thread.

SCHED_FIFO2

The policy is the same as for SCHED_FIFO, except that it allows a thread which has slept for only a short amount of time to be put at the head of its run queue when it is awakened. This time period is the affinity limit (tunable with **schedtune -a**). This policy is only available beginning with AIX 4.3.3.

SCHED_FIFO3

A thread whose scheduling policy is set to SCHED_FIFO3 is always put at the head of a run queue. To prevent a thread belonging to SCHED_FIFO2 scheduling policy from being put ahead of SCHED_FIFO3, the run queue parameters are changed when a SCHED_FIFO3 thread is enqueued, so that no thread belonging to SCHED_FIFO2 will satisfy the criterion that enables it to join the head of the run queue. This policy is only available beginning with AIX 4.3.3.

The scheduling policies are set with the **thread_setsched()** system call and are only effective for the calling thread. However, a thread can be set to the SCHED_RR scheduling policy by issuing a **setpri()** call specifying the process ID; the caller of **setpri()** and the target of **setpri()** do not have to match.

Only processes that have root authority can issue the **setpri()** system call. Only threads that have root authority can change the scheduling policy to any of the SCHED_FIFO options or SCHED_RR. If the scheduling policy is SCHED_OTHER, the priority parameter is ignored by the **thread_setsched()** subroutine.

Threads are primarily of interest for applications that currently consist of several asynchronous processes. These applications might impose a lighter load on the system if converted to a multithreaded structure.

Scheduler Run Queue

The scheduler maintains a run queue of all of the threads that are ready to be dispatched. The following illustration depicts the run queue symbolically.

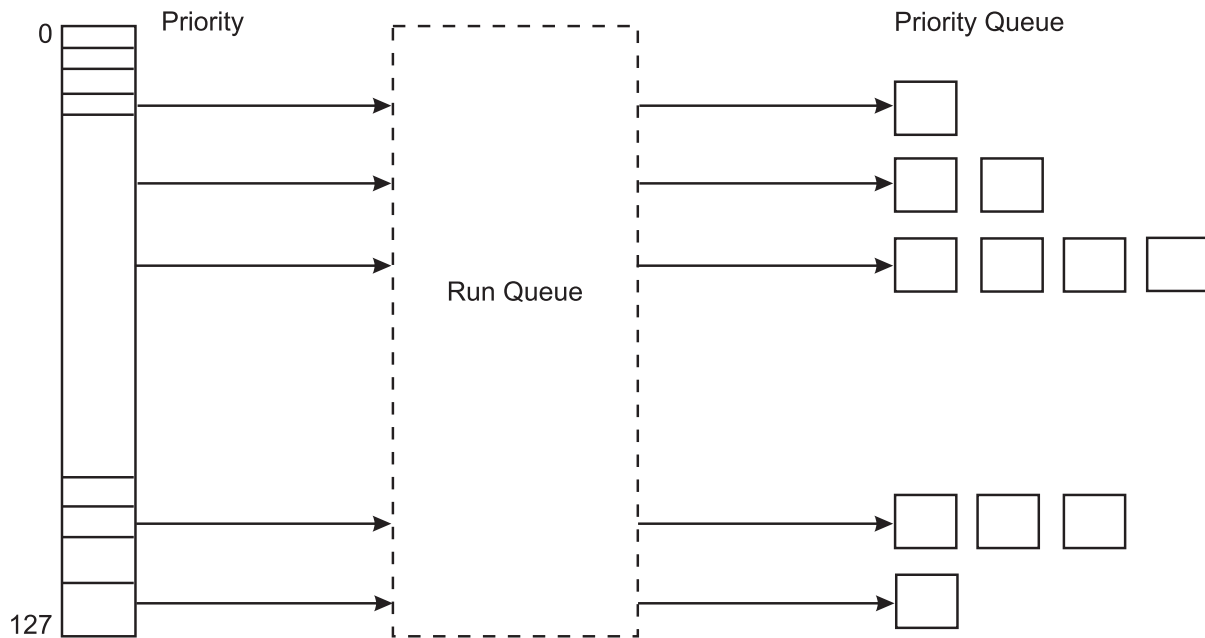

Figure 7. Run Queue. This illustration simply shows how threads with a lower priority value are passed through the run queue before threads with a higher priority value. The range of possible priority values is 0 to 127 which directly relate to a total of 128 total run queues.

All the dispatchable threads of a given priority occupy positions in the run queue.

The fundamental dispatchable entity of the scheduler is the thread. AIX 5.1 maintains 256 run queues (128 in AIX 4.3 and prior releases). In AIX 5.1, run queues relate directly to the range of possible values (0 through 255) for the priority field for each thread. This method makes it easier for the scheduler to determine which thread is most favored to run. Without having to search a single large run queue, the scheduler consults a mask where a bit is on to indicate the presence of a ready-to-run thread in the corresponding run queue.

The priority value of a thread changes rapidly and frequently. The constant movement is due to the way that the scheduler recalculates priorities. This is not true, however, for fixed-priority threads.

Starting with AIX 4.3.3, each CPU has its own run queue. The run queue values reported in the performance tools will be the sum of all the threads in each run queue. Having a per-CPU run queue saves overhead on dispatching locks and improves overall processor affinity. Threads will tend to stay on the same CPU more often. If a thread becomes runnable because of an event on another CPU than the one in which the newly runnable thread had been running on, then this thread would only get dispatched immediately if there was an idle CPU. No preemption occurs until the processor's state can be examined (such as an interrupt on this thread's CPU).

An environment variable called `RT_GRQ` exists, that, if set to `ON`, will cause this thread to be on a global run queue. In that case, the global run queue is searched to see which thread has the best priority. This can improve performance for threads that are interrupt driven. Threads that are running at fixed priority are placed on the global run queue if `schedtune -F` is set to 1.

The average number of threads in the run queue can be seen in the first column of the `vmstat` command output. If you divide this number by the number of CPUs, the result is the average number of threads that can be run on each CPU. If this value is greater than one, these threads must wait their turn for the CPU (the greater the number, the more likely it is that performance delays are noticed).

When a thread is moved to the end of the run queue (for example, when the thread has control at the end of a time slice), it is moved to a position after the last thread in the queue that has the same priority value.

Scheduler CPU Time Slice

The CPU time slice is the amount of time a SCHED_RR thread can absorb before the scheduler switches to another thread at the same priority. You can use the **-t** option of the **schedtune** command to increase the number of clock ticks in the time slice by 10 millisecond increments (see Modifying the Scheduler Time Slice with the schedtune Command).

Note: The time slice is not a guaranteed amount of processor time. It is the longest time that a thread can be in control before it faces the possibility of being replaced by another thread. There are many ways in which a thread can lose control of the CPU before it has had control for a full time slice.

Mode Switching

A user process undergoes a mode switch when it needs access to system resources. This is implemented through the system call interface or by interrupts such as page faults. There are two modes:

- User mode
- Kernel mode

CPU time spent in user mode (application and shared libraries) is reflected as user time in the output of commands such as the **vmstat**, **iostat**, and **sar** commands. CPU time spent in kernel mode is reflected as system time in the output of these commands.

User Mode

Programs that execute in the user protection domain are user processes. Code that executes in this protection domain executes in user execution mode, and has the following access:

- Read/write access to user data in the process private region
- Read access to the user text and shared text regions
- Access to shared data regions using the shared memory functions

Programs executing in the user protection domain do not have access to the kernel or kernel data segments, except indirectly through the use of system calls. A program in this protection domain can only affect its own execution environment and executes in the process or unprivileged state.

Kernel Mode

Programs that execute in the kernel protection domain include interrupt handlers, kernel processes, the base kernel, and kernel extensions (device driver, system calls and file systems). This protection domain implies that code executes in kernel execution mode, and has the following access:

- Read/write access to the global kernel address space
- Read/write access to the kernel data in the process region when executing within a process

Kernel services must be used to access user data within the process address space.

Programs executing in this protection domain can affect the execution environments of all programs, because they have the following characteristics:

- They can access global system data.
- They can use kernel services.
- They are exempt from all security restraints.
- They execute in the processor privileged state.

Mode Switches

The use of a system call by a user-mode process allows a kernel function to be called from user mode. Access to functions that directly or indirectly invoke system calls is typically provided by programming libraries, which provide access to operating system functions.

Mode switches should be differentiated from the context switches seen in the output of the **vmstat** (cs column) and **sar** (cswch/s) commands. A context switch occurs when the currently running thread is different from the previously running thread on that CPU.

The scheduler performs a context switch when any of the following occurs:

- A thread must wait for a resource (voluntarily), such as disk I/O, network I/O, sleep, or locks.
- A higher priority thread wakes up (involuntarily).
- The thread has used up its time slice (usually 10 ms).

Context switch time, system calls, device interrupts, NFS I/O, and any other activity in the kernel is considered as system time.

Performance Overview of the Virtual Memory Manager (VMM)

The virtual address space is partitioned into segments. A segment is a 256 MB, contiguous portion of the virtual-memory address space into which a data object can be mapped.

Process addressability to data is managed at the segment (or object) level so that a segment can be shared between processes or maintained as private. For example, processes can share code segments yet have separate and private data segments.

Real-Memory Management

Virtual-memory segments are partitioned into fixed-size units called *pages*. The page size is 4096 bytes. Each page in a segment can be in real memory (RAM), or stored on disk until it is needed. Similarly, real memory is divided into 4096-byte page frames. The role of the VMM is to manage the allocation of real-memory page frames and to resolve references by the program to virtual-memory pages that are not currently in real memory or do not yet exist (for example, when a process makes the first reference to a page of its data segment).

Because the amount of virtual memory that is in use at any given instant can be larger than real memory, the VMM must store the surplus on disk. From the performance standpoint, the VMM has two, somewhat opposed, objectives:

- Minimize the overall processor-time and disk-bandwidth cost of the use of virtual memory
- Minimize the response-time cost of page faults

In pursuit of these objectives, the VMM maintains a *free list* of page frames that are available to satisfy a page fault. The VMM uses a page-replacement algorithm to determine which virtual-memory pages currently in memory will have their page frames reassigned to the free list. The page-replacement algorithm uses several mechanisms:

- Virtual-memory segments are classified into either persistent segments or working segments.
- Virtual-memory segments are classified as containing either computational or file memory.
- Virtual-memory pages whose access causes a page fault are tracked.
- Page faults are classified as new-page faults or as repage faults.
- Statistics are maintained on the rate of repage faults in each virtual-memory segment.
- User-tunable thresholds influence the page-replacement algorithm's decisions.

The following sections describe the free list and the page-replacement mechanisms in more detail.

Free List

The VMM maintains a logical list of free page frames that it uses to accommodate page faults. In most environments, the VMM must occasionally add to the free list by reassigning some page frames owned by running processes. The virtual-memory pages whose page frames are to be reassigned are selected by the VMM's page-replacement algorithm. The VMM thresholds determine the number of frames reassigned.

Persistent versus Working Segments

The pages of a persistent segment have permanent storage locations on disk. Files containing data or executable programs are mapped to persistent segments. Because each page of a persistent segment has a permanent disk storage location, the VMM writes the page back to that location when the page has been changed and can no longer be kept in real memory. If the page has not changed when selected for placement on a free list, no I/O is required. If the page is referenced again later, a new copy is read in from its permanent disk-storage location.

Working segments are transitory, exist only during their use by a process, and have no permanent disk-storage location. Process stack and data regions are mapped to working segments, as are the kernel text segment, the kernel-extension text segments, as well as the shared-library text and data segments. Pages of working segments must also have disk-storage locations to occupy when they cannot be kept in real memory. The disk-paging space is used for this purpose.

The following illustration shows the relationship between some of the types of segments and the locations of their pages on disk. It also shows the actual (arbitrary) locations of the pages when they are in real memory.

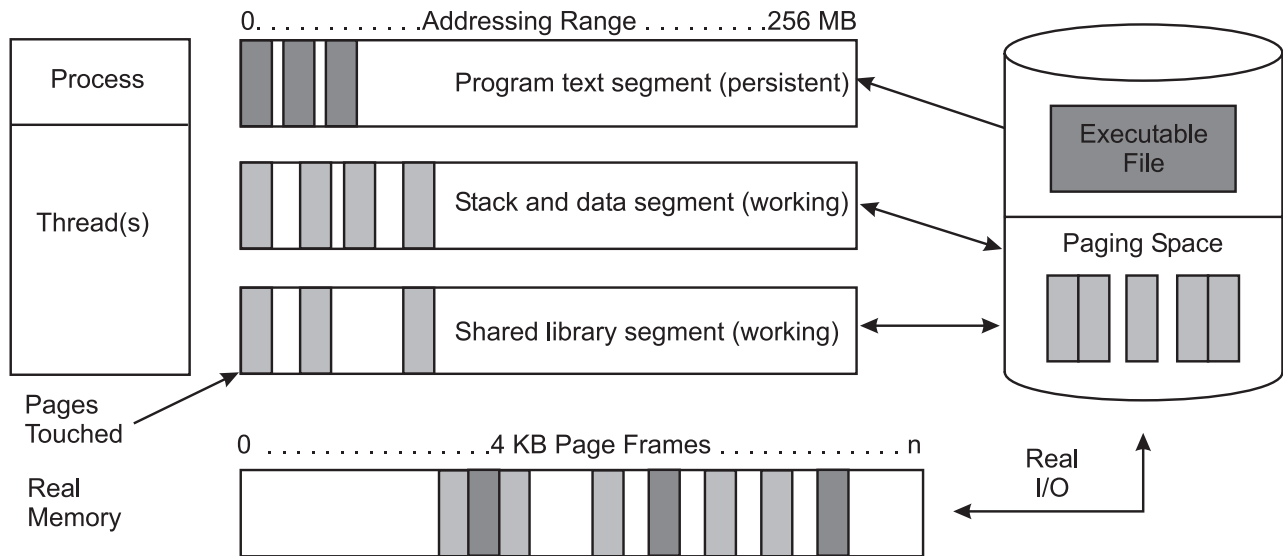

Figure 8. Persistent and Working Storage Segments. The following illustration shows the relationship between some of the types of segments and the locations of their pages on disk. It also shows the actual (arbitrary) locations of the pages when they are in real memory. Working segments are transitory, meaning they exist only during their use by a process and have no permanent disk-storage location. Process stack and data regions are mapped to working segments, as are the kernel text segment, the kernel-extension text segments, and the shared-library text and data segments. Pages of working segments must also have disk-storage locations to occupy when they cannot be kept in real memory. The disk-paging space is used for this purpose.

Persistent-segment types are further classified. *Client segments* are used to map remote files (for example, files that are being accessed through NFS), including remote executable programs. Pages from client segments are saved and restored over the network to their permanent file location, not on the local-disk paging space. *Journalled and deferred segments* are persistent segments that must be atomically updated. If a page from a journalled or deferred segment is selected to be removed from real memory (paged out), it must be written to disk paging space unless it is in a state that allows it to be committed (written to its permanent file location).

Computational versus File Memory

Computational memory, also known as computational pages, consists of the pages that belong to working-storage segments or program text (executable files) segments.

File memory (or file pages) consists of the remaining pages. These are usually pages from permanent data files in persistent storage.

Page Replacement

When the number of available real memory frames on the free list becomes low, a page stealer is invoked. A page stealer moves through the Page Frame Table (PFT), looking for pages to steal.

The PFT includes flags to signal which pages have been referenced and which have been modified. If the page stealer encounters a page that has been referenced, it does not steal that page, but instead, resets the reference flag for that page. The next time the clock hand (page stealer) passes that page and the reference bit is still off, that page is stolen. A page that was not referenced in the first pass is immediately stolen.

The modify flag indicates that the data on that page has been changed since it was brought into memory. When a page is to be stolen, if the modify flag is set, a pageout call is made before stealing the page. Pages that are part of working segments are written to paging space; persistent segments are written to disk.

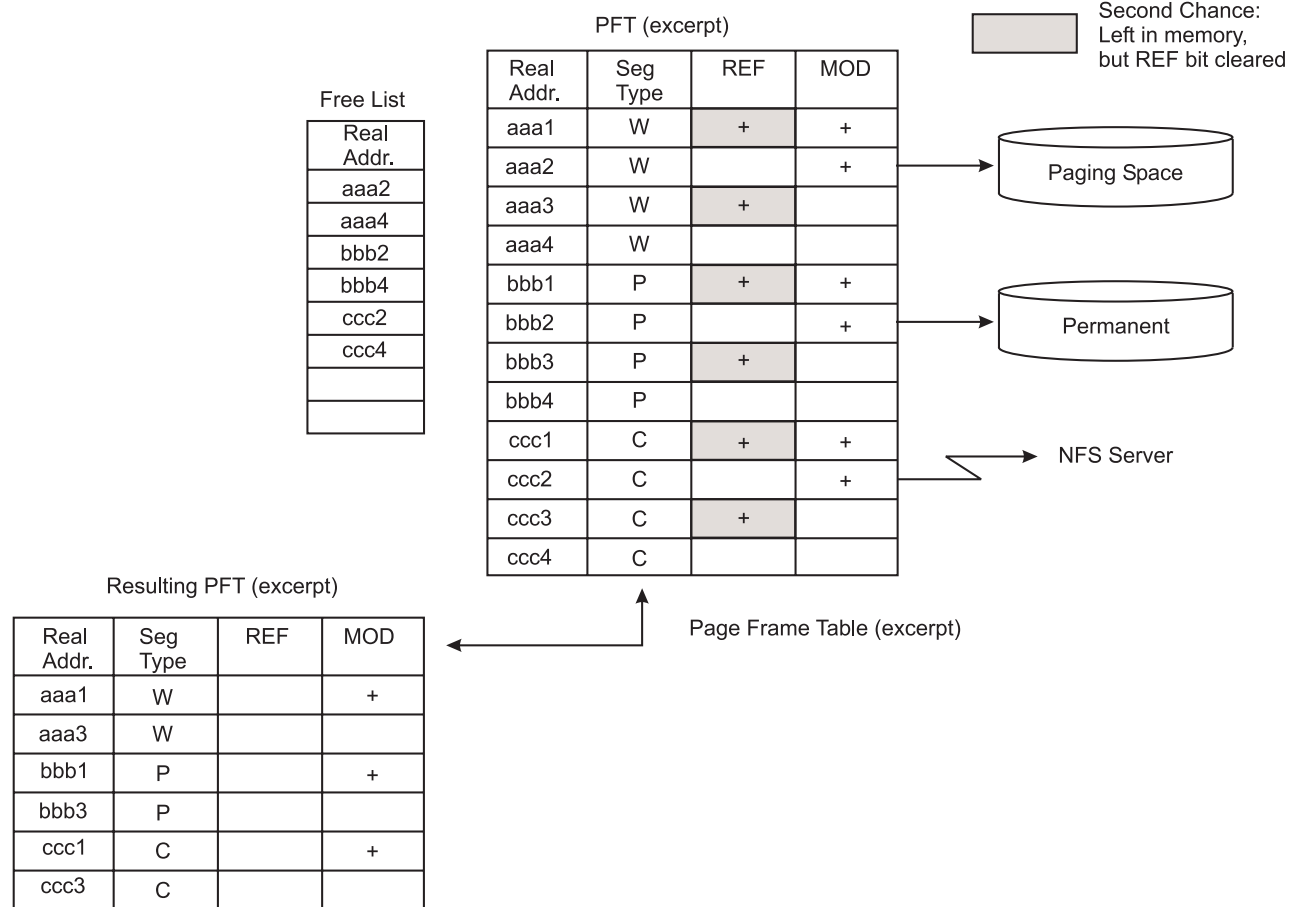

Figure 9. Page Replacement Example. The illustration consists of excerpts from three tables. The first table is the page frame table with four columns that contain the real address, the segment type, a reference flag, and a modify flag. A second table is called the free list table and contains addresses of all free pages. The last table represents the resulting page frame table after all of the free addresses have been removed.

In addition to the page-replacement, the algorithm keeps track of both new page faults (referenced for the first time) and repage faults (referencing pages that have been paged out), by using a history buffer that

contains the IDs of the most recent page faults. It then tries to balance file (persistent data) page outs with computational (working storage or program text) page outs.

When a process exits, its working storage is released immediately and its associated memory frames are put back on the free list. However, any files that the process may have opened can stay in memory.

Page replacement is done directly within the scope of the thread if running on a uniprocessor. On a multiprocessor system, page replacement is done through the **lrud** kernel process, which is dispatched to a CPU when the **minfree** threshold has been reached. Starting with AIX 4.3.3, the **lrud** kernel process is multithreaded with one thread per memory pool. Real memory is split into evenly sized memory pools based on the number of CPUs and the amount of RAM. The number of memory pools will be as follows:

- MAX (Number of CPUs/8, RAM in GB/16), but not more than the number of CPUs and not less than 1

In AIX 4.3.3 and later use the **vmtune -m <number of memory pools>** command to change the number of memory pools that will be configured at system boot. The values for **minfree** and **maxfree** in the **vmtune** command output will be the sum of the **minfree** and **maxfree** for each memory pool.

Repaging

A page fault is considered to be either a new page fault or a repage fault. A new page fault occurs when there is no record of the page having been referenced recently. A repage fault occurs when a page that is known to have been referenced recently is referenced again, and is not found in memory because the page has been replaced (and perhaps written to disk) since it was last accessed.

A perfect page-replacement policy would eliminate repage faults entirely (assuming adequate real memory) by always stealing frames from pages that are not going to be referenced again. Thus, the number of repage faults is an inverse measure of the effectiveness of the page-replacement algorithm in keeping frequently reused pages in memory, thereby reducing overall I/O demand and potentially improving system performance.

To classify a page fault as new or repage, the VMM maintains a repage history buffer that contains the page IDs of the *N* most recent page faults, where *N* is the number of frames that the memory can hold. For example, 512 MB memory requires a 128 KB repage history buffer. At page-in, if the page's ID is found in the repage history buffer, it is counted as a repage. Also, the VMM estimates the computational-memory repaging rate and the file-memory repaging rate separately by maintaining counts of repage faults for each type of memory. The repaging rates are multiplied by 0.9 each time the page-replacement algorithm runs, so that they reflect recent repaging activity more strongly than historical repaging activity.

VMM Thresholds

Several numerical thresholds define the objectives of the VMM. When one of these thresholds is breached, the VMM takes appropriate action to bring the state of memory back within bounds. This section discusses the thresholds that the system administrator can alter through the **vmtune** command.

The number of page frames on the free list is controlled by the following parameters:

minfree

Minimum acceptable number of real-memory page frames in the free list. When the size of the free list falls below this number, the VMM begins stealing pages. It continues stealing pages until the size of the free list reaches **maxfree**.

maxfree

Maximum size to which the free list will grow by VMM page-stealing. The size of the free list may exceed this number as a result of processes terminating and freeing their working-segment pages or the deletion of files that have pages in memory.

The VMM attempts to keep the size of the free list greater than or equal to **minfree**. When page faults or system demands cause the free list size to fall below **minfree**, the page-replacement algorithm runs. The

size of the free list must be kept above a certain level (the default value of **minfree**) for several reasons. For example, the operating system's sequential-prefetch algorithm requires several frames at a time for each process that is doing sequential reads. Also, the VMM must avoid deadlocks within the operating system itself, which could occur if there were not enough space to read in a page that was required to free a page frame.

The following thresholds are expressed as percentages. They represent the fraction of the total real memory of the machine that is occupied by file pages (pages of noncomputational segments).

minperm

If the percentage of real memory occupied by file pages falls below this level, the page-replacement algorithm steals both file and computational pages, regardless of repage rates.

maxperm

If the percentage of real memory occupied by file pages rises above this level, the page-replacement algorithm steals only file pages.

When the percentage of real memory occupied by file pages is between **minperm** and **maxperm**, the VMM normally steals only file pages, but if the repaging rate for file pages is higher than the repaging rate for computational pages, computational pages are stolen as well.

The main intent of the page-replacement algorithm is to ensure that computational pages are given fair treatment. For example, the sequential reading of a long data file into memory should not cause the loss of program text pages that are likely to be used again soon. The page-replacement algorithm's use of the thresholds and repaging rates ensures that both types of pages get treated fairly, with a slight bias in favor of computational pages.

VMM Memory Load Control Facility

A process requires real-memory pages to execute. When a process references a virtual-memory page that is on disk, because it either has been paged-out or has never been read, the referenced page must be paged-in and, on average, one or more pages must be paged out (if replaced pages had been modified), creating I/O traffic and delaying the progress of the process.

The operating system attempts to steal real memory from pages that are unlikely to be referenced in the near future, through the page-replacement algorithm. A successful page-replacement algorithm allows the operating system to keep enough processes active in memory to keep the CPU busy. But at some level of competition for memory, no pages are good candidates for paging out to disk because they will all be reused in the near future by the active set of processes. This situation depends on the following:

- Total amount of memory in the system
- The number of processes
- The time-varying memory requirements of each process
- The page-replacement algorithm

When this happens, continuous paging-in and paging-out occurs. This condition is called *thrashing*. Thrashing results in incessant I/O to the paging disk and causes each process to encounter a page fault almost as soon as it is dispatched, with the result that none of the processes make any significant progress.

The most destructive aspect of thrashing is that, although thrashing may have been triggered by a brief, random peak in workload (such as all of the users of a system happening to press Enter in the same second), the system might continue thrashing for an indefinitely long time.

The operating system has a memory load-control algorithm that detects when the system is starting to thrash and then suspends active processes and delays the initiation of new processes for a period of time. Five parameters set rates and bounds for the algorithm. The default values of these parameters have

been chosen to be "fail safe" across a wide range of workloads. In AIX Version 4, memory load control is disabled by default on systems that have available memory frames that add up to greater than or equal to 128 MB.

Memory Load Control Algorithm

The memory load control mechanism assesses, once per second, whether sufficient memory is available for the set of active processes. When a memory-overcommitment condition is detected, some processes are suspended, decreasing the number of active processes and thereby decreasing the level of memory overcommitment.

When a process is suspended, all of its threads are suspended when they reach a suspendable state. The pages of the suspended processes quickly become stale and are paged out by the page-replacement algorithm, releasing enough page frames to allow the remaining active processes to progress. During the interval in which existing processes are suspended, newly created processes are also suspended, preventing new work from entering the system. Suspended processes are not reactivated until a subsequent interval passes during which no potential thrashing condition exists. Once this safe interval has passed, the threads of the suspended processes are gradually reactivated.

Memory load-control parameters specify the following:

- The system memory overcommitment threshold (**schedtune -h**)
- The number of seconds required to make a safe interval (**schedtune -w**)
- The individual process memory overcommitment threshold by which an individual process is qualified as a suspension candidate (**schedtune -p**)
- The minimum number of active processes when processes are being suspended (**schedtune -m**)
- The minimum number of elapsed seconds of activity for a process after reactivation (**schedtune -e**)

For information on setting and tuning these parameters, see Tuning VMM Memory Load Control with the schedtune Command.

Once per second, the scheduler (process 0) examines the values of all the above measures that have been collected over the preceding one-second interval, and determines if processes are to be suspended or activated. If processes are to be suspended, every process eligible for suspension by the **-p** and **-e** parameter test is marked for suspension. When that process next receives the CPU in user mode, it is suspended (unless doing so would reduce the number of active processes below the **-m** value). The user-mode criterion is applied so that a process is ineligible for suspension during critical system activities performed on its behalf. If, during subsequent one-second intervals, the thrashing criterion is still being met, additional process candidates meeting the criteria set by **-p** and **-e** are marked for suspension. When the scheduler subsequently determines that the safe-interval criterion has been met and processes are to be reactivated, some number of suspended processes are put on the run queue (made active) every second.

Suspended processes are reactivated by:

1. Priority
2. The order in which they were suspended

The suspended processes are not all reactivated at once. A value for the number of processes reactivated is selected by a formula that recognizes the number of then-active processes and reactivates either one-fifth of the number of then-active processes or a monotonically increasing lower bound, whichever is greater. This cautious strategy results in increasing the degree of multiprogramming roughly 20 percent per second. The intent of this strategy is to make the rate of reactivation relatively slow during the first second after the safe interval has expired, while steadily increasing the reintroduction rate in subsequent seconds. If the memory-overcommitment condition recurs during the course of reactivating processes, the following occur:

- Reactivation is halted

- The marked-to-be reactivated processes are again marked suspended
- Additional processes are suspended in accordance with the above rules

Allocation and Reclamation of Paging Space Slots

The operating system supports three allocation methods for working storage, also referred to as *paging-space slots*, as follows:

- Late allocation
- Early allocation
- Deferred allocation

Note: Paging-space slots are only released by process (not thread) termination or by the **disclaim()** system call. The slots are not released by the **free()** system call.

Late Allocation Algorithm

Prior to AIX 4.3.2 with the late allocation algorithm, a paging slot is allocated to a page of virtual memory only when that page is first touched. That is the first time that the page's content is of interest to the executing program.

Many programs exploit late allocation by allocating virtual-memory address ranges for maximum-sized structures and then only using as much of the structure as the situation requires. The pages of the virtual-memory address range that are never accessed never require real-memory frames or paging-space slots.

This technique does involve some degree of risk. If all of the programs running in a machine happened to encounter maximum-size situations simultaneously, paging space might be exhausted. Some programs might not be able to continue to completion.

Early Allocation Algorithm

The second operating system's paging-space-slot-allocation method is intended for use in installations where this situation is likely, or where the cost of failure to complete is intolerably high. Aply called early allocation, this algorithm causes the appropriate number of paging-space slots to be allocated at the time the virtual-memory address range is allocated, for example, with the **malloc()** subroutine. If there are not enough paging-space slots to support the **malloc()** subroutine, an error code is set. The early-allocation algorithm is invoked as follows:

```
# export PSALLOC=early
```

This example causes all future programs to be executed in the environment to use early allocation. The currently executing shell is not affected.

Early allocation is of interest to the performance analyst mainly because of its paging-space size implications. If early allocation is turned on for those programs, paging-space requirements can increase many times. Whereas the normal recommendation for paging-space size is at least twice the size of the system's real memory, the recommendation for systems that use **PSALLOC=early** is at least four times the real memory size. Actually, this is just a starting point. Analyze the virtual storage requirements of your workload and allocate paging spaces to accommodate them. As an example, at one time, the AIXwindows server required 250 MB of paging space when run with early allocation.

Deferred Allocation Algorithm

The third operating system's paging-space-slot-allocation method is the default beginning with AIX 4.3.2 Deferred Page Space Allocation (DPSA) policy delays allocation of paging space until it is necessary to page out the page, which results in no wasted paging space allocation. This method can save huge amounts of paging space, which means disk space.

On some systems, paging space might not ever be needed even if all the pages accessed have been touched. This situation is most common on systems with very large amount of RAM. However, this may result in overcommitment of paging space in cases where more virtual memory than available RAM is accessed.

To disable DPSA and preserve the Late Page Space Allocation policy, run the following command:

```
# /usr/samples/kernel/vmtune -d 0
```

To activate DPSA, run the following command:

```
# /usr/samples/kernel/vmtune -d 1
```

For further information, see [Choosing a Page Space Allocation Method and Placement and Sizes of Paging Spaces](#).

Performance Overview of Fixed-Disk Storage Management

The following illustration shows the hierarchy of structures used by the operating system to manage fixed-disk storage. Each individual disk drive, called a physical volume (PV), has a name, such as **/dev/hdisk0**. If the physical volume is in use, it belongs to a volume group (VG). All of the physical volumes in a volume group are divided into physical partitions (PPs) of the same size (by default, 4 MB in volume groups that include physical volumes smaller than 4 GB; 8 MB or more with bigger disks).

For space-allocation purposes, each physical volume is divided into five regions. See [Position on Physical Volume](#) for more information. The number of physical partitions in each region varies, depending on the total capacity of the disk drive.

Figure 10. Organization of Fixed-Disk Data (Unmirrored). The illustration shows the hierarchy of a physical volume that is partitioned into one or more logical volumes. These partitions or logical volumes contain file systems with directory structures which contain individual files. Files are written to blocks contained in tracks on the storage media and these blocks are usually not contiguous. Disk fragmenting occurs when data gets erased and new data files are written to the empty blocks that are randomly scattered around multiple tracks on the media.

Within each volume group, one or more logical volumes (LVs) are defined. Each logical volume consists of one or more logical partitions. Each logical partition corresponds to at least one physical partition. If mirroring is specified for the logical volume, additional physical partitions are allocated to store the additional copies of each logical partition. Although the logical partitions are numbered consecutively, the underlying physical partitions are not necessarily consecutive or contiguous.

Logical volumes can serve a number of system purposes, such as paging, but each logical volume that holds ordinary system data or user data or programs contains a single journaled file system (JFS). Each

JFS consists of a pool of page-size (4096-byte) blocks. When data is to be written to a file, one or more additional blocks are allocated to that file. These blocks may or may not be contiguous with one another and with other blocks previously allocated to the file.

In AIX Version 4, a given file system can be defined as having a fragment size of less than 4096 bytes. Fragment size can be 512, 1024, or 2048 bytes, allowing small files to be stored more efficiently.

For purposes of illustration, the previous figure shows a bad (but not the worst possible) situation that might arise in a file system that had been in use for a long period without reorganization. The **/op/filename** file is physically recorded on a large number of blocks that are physically distant from one another. Reading the file sequentially would result in many time-consuming seek operations.

While an operating system's file is conceptually a sequential and contiguous string of bytes, the physical reality might be very different. Fragmentation may arise from multiple extensions to logical volumes as well as allocation/release/reallocation activity within a file system. A file system is fragmented when its available space consists of large numbers of small chunks of space, making it impossible to write out a new file in contiguous blocks.

Access to files in a highly fragmented file system may result in a large number of seeks and longer I/O response times (seek latency dominates I/O response time). For example, if the file is accessed sequentially, a file placement that consists of many, widely separated chunks requires more seeks than a placement that consists of one or a few large contiguous chunks. If the file is accessed randomly, a placement that is widely dispersed requires longer seeks than a placement in which the file's blocks are close together.

The effect of a file's placement on I/O performance diminishes when the file is buffered in memory. When a file is opened in the operating system, it is mapped to a persistent data segment in virtual memory. The segment represents a virtual buffer for the file; the file's blocks map directly to segment pages. The VMM manages the segment pages, reading file blocks into segment pages upon demand (as they are accessed). There are several circumstances that cause the VMM to write a page back to its corresponding block in the file on disk; but, in general, the VMM keeps a page in memory if it has been accessed recently. Thus, frequently accessed pages tend to stay in memory longer, and logical file accesses to the corresponding blocks can be satisfied without physical disk accesses.

At some point, the user or system administrator can choose to reorganize the placement of files within logical volumes and the placement of logical volumes within physical volumes to reduce fragmentation and to more evenly distribute the total I/O load. Chapter 8. Monitoring and Tuning Disk I/O Use contains further details about detecting and correcting disk placement and fragmentation problems.

Sequential-Access Read Ahead

The VMM tries to anticipate the future need for pages of a sequential file by observing the pattern in which a program is accessing the file. When the program accesses two successive pages of the file, the VMM assumes that the program will continue to access the file sequentially, and the VMM schedules additional sequential reads of the file. These reads are overlapped with the program processing, and will make the data available to the program sooner than if the VMM had waited for the program to access the next page before initiating the I/O. The number of pages to be read ahead is determined by two VMM thresholds:

minpgahead

Number of pages read ahead when the VMM first detects the sequential access pattern. If the program continues to access the file sequentially, the next read ahead will be for 2 times **minpgahead**, the next for 4 times **minpgahead**, and so on until the number of pages reaches **maxpgahead**.

maxpgahead

Maximum number of pages the VMM will read ahead in a sequential file.

If the program deviates from the sequential-access pattern and accesses a page of the file out of order, sequential read ahead is terminated. It will be resumed with **minpgahead** pages if the VMM detects a resumption of sequential access by the program. The values of **minpgahead** and **maxpgahead** can be set with the **vmtune** command. Sequential Read-Ahead contains further details about read ahead and the ground rules for changing the thresholds.

Write Behind

To increase write performance, limit the number of dirty file pages in memory, reduce system overhead, and minimize disk fragmentation, the file system divides each file into 16 KB partitions. The pages of a given partition are not written to disk until the program writes the first byte of the next 16 KB partition. At that point, the file system forces the four dirty pages of the first partition to be written to disk. The pages of data remain in memory until their frames are reused, at which point no additional I/O is required. If a program accesses any of the pages before their frames are reused, no I/O is required.

If a large number of dirty file pages remain in memory and do not get reused, the **sync** daemon writes them to disk, which might result in abnormal disk utilization. To distribute the I/O activity more efficiently across the workload, write-behind can be turned on to tell the system how many pages to keep in memory before writing them to disk. The write-behind threshold is on a per-file basis, which causes pages to be written to disk before the **sync** daemon runs. The I/O is spread more evenly throughout the workload.

There are two types of write-behind: sequential and random. The size of the write-behind partitions and the write-behind threshold can be changed with the **vmtune** command (see VMM Write-Behind).

Memory Mapped Files and Write Behind

Normal files are automatically mapped to segments to provide mapped files. This means that normal file access bypasses traditional kernel buffers and block I/O routines, allowing files to use more memory when the extra memory is available (file caching is not limited to the declared kernel buffer area).

Files can be mapped explicitly with the **shmat()** or **mmap()** subroutines, but this provides no additional memory space for their caching. Applications that use the **shmat()** or **mmap()** subroutines to map a file explicitly and access it by address rather than by the **read()** and **write()** subroutines may avoid some path length of the system-call overhead, but they lose the benefit of the system write-behind feature.

When applications do not use the **write()** subroutine, modified pages tend to accumulate in memory and be written randomly when purged by the VMM page-replacement algorithm or the **sync** daemon. This results in many small writes to the disk that cause inefficiencies in CPU and disk utilization, as well as fragmentation that might slow future reads of the file.

Disk-I/O Pacing

Because most writes are asynchronous, FIFO I/O queues of several megabytes can build up, which can take several seconds to complete. The performance of an interactive process is severely impacted if every disk read spends several seconds working its way through the queue. In response to this problem, the VMM has an option called I/O pacing to control writes.

I/O pacing does not change the interface or processing logic of I/O. It simply limits the number of I/Os that can be outstanding against a file. When a process tries to exceed that limit, it is suspended until enough outstanding requests have been processed to reach a lower threshold. Using Disk-I/O Pacing describes I/O pacing in more detail.

Chapter 3. Introduction to Multiprocessing

At any given time, a technological limit exists on the speed with which a single processor chip can operate. If a system's workload cannot be handled satisfactorily by a single processor, one response is to apply multiple processors to the problem.

The success of this response depends not only on the skill of the system designers, but also on whether the workload is amenable to multiprocessing. In terms of human tasks, adding people might be a good idea if the task is answering calls to a toll-free number, but is dubious if the task is driving a car.

If improved performance is the objective of a proposed migration from a uniprocessor to a multiprocessor system, the following conditions must be true:

- The workload is processor-limited and has saturated its uniprocessor system.
- The workload contains multiple processor-intensive elements, such as transactions or complex calculations, that can be performed simultaneously and independently.
- The existing uniprocessor cannot be upgraded or replaced with another uniprocessor of adequate power.

Although unchanged single-thread applications normally function correctly in a multiprocessor environment, their performance often changes in unexpected ways. Migration to a multiprocessor can improve the throughput of a system, and can improve the execution time of complex, multithreaded applications, but seldom improves the response time of individual, single-thread commands.

Getting the best possible performance from a multiprocessor system requires an understanding of the operating-system and hardware-execution dynamics that are unique to the multiprocessor environment.

This chapter includes the following major sections:

- Symmetrical Multiprocessor (SMP) Concepts and Architecture
- SMP Performance Issues
- SMP Workloads
- SMP Thread Scheduling
- Thread Tuning
- SMP Tools

Symmetrical Multiprocessor (SMP) Concepts and Architecture

As with any change that increases the complexity of the system, the use of multiple processors generates design considerations that must be addressed for satisfactory operation and performance. The additional complexity gives more scope for hardware/software tradeoffs and requires closer hardware/software design coordination than in uniprocessor systems. The different combinations of design responses and tradeoffs give rise to a wide variety of multiprocessor system architectures.

This section describes the main design considerations of multiprocessor systems and the hardware responses to those considerations.

Types of Multiprocessing

Several categories of multiprocessing (MP) systems exist, as described below:

Shared Nothing MP (pure cluster)

Each processor is a complete stand-alone machine and runs a copy of the operating system. The processors share nothing (each has its own memory, caches, and disks), but they are interconnected.

When LAN-connected, processors are loosely coupled. When connected by a switch, the processors are tightly coupled. Communication between processors is done through message-passing.

The advantages of such a system are very good scalability and high availability. The disadvantages of such a system are an unfamiliar programming model (message passing).

Shared Disks MP

Processors have their own memory and cache. The processors run in parallel and share disks. Each processor runs a copy of the operating system and the processors are loosely coupled (connected through LAN). Communication between processors is done through message-passing.

The advantages of shared disks are that part of a familiar programming model is retained (disk data is addressable and coherent, memory is not), and high availability is much easier than with shared-memory systems. The disadvantages are limited scalability due to bottlenecks in physical and logical access to shared data.

Shared Memory Cluster (SMC)

All of the processors in a shared memory cluster have their own resources (main memory, disks, I/O) and each processor runs a copy of the operating system. Processors are tightly coupled (connected through a switch). Communication between the processors is done through shared memory.

Shared Memory MP

All of the processors are tightly coupled inside the same box with a high-speed bus or a switch. The processors share the same global memory, disks, and I/O devices. Only one copy of the operating system runs across all of the processors, and the operating system must be designed to exploit this architecture (multithreaded operating system).

SMPs have several advantages:

- They are a cost-effective way to increase throughput.
- They offer a single system image since the Operating System is shared between all the processors (administration is easy).
- They apply multiple processors to a single problem (parallel programming).
- Load balancing is done by the operating system.
- The uniprocessor (UP) programming model can be used in an SMP.
- They are scalable for shared data.
- All data is addressable by all the processors and kept coherent by the hardware snooping logic.
- There is no need to use message-passing libraries to communicate between processors because communication is done through the global shared memory.
- More power requirements can be solved by adding more processors to the system. However, you must set realistic expectations about the increase in performance when adding more processors to an SMP system.
- More and more applications and tools are available today. Most UP applications can run on or are ported to SMP architecture.

There are some limitations of SMP systems, as follows:

- Because SMP systems need MP-enabled processors, some floating point processors (such as POWER2 processors that are not MP-enabled) cannot be used in SMPs.
- There are limits on scalability due to cache coherency, locking mechanism, shared objects, and others.
- There is a need for new skills to exploit multiprocessors, such as threads programming and device drivers programming.

Symmetrical versus Asymmetrical Multiprocessors

Perhaps the most fundamental decision in designing a multiprocessor system is whether the system will be symmetrical or asymmetrical.

Asymmetrical Multiprocessors

In an asymmetrical multiprocessor system, the processors are assigned different roles. One processor may handle I/O, while others execute user programs, and so forth. Typically one processor is designed as the master and the others are the slaves. The master is a general purpose processor and performs input and output operations as well as computation. The slave processors perform only computation. Use of a slave may be poor if the master does not service slave requests efficiently. I/O-bound jobs may not run efficiently, because only the master executes the I/O operations. Failure of the master is catastrophic. Additional advantages and disadvantages of this approach are as follows:

- By restricting certain operations to a single processor, some forms of data serialization and cache coherency problems can be reduced or avoided. Some parts of the software may be able to operate as though they were running in a uniprocessor.
- In some situations, I/O-operation or application-program processing may be faster because it does not have to contend with other parts of the operating system or the workload for access to a processor.
- In other situations, I/O-operation or application-program processing can be slowed because not all of the processors are available to handle peak loads.
- The existence of a single processor handling specific work creates a unique point of failure for the system as a whole.

Symmetrical Multiprocessors

In a symmetrical multiprocessor system, all of the processors are essentially identical and perform identical functions as follows:

- All of the processors work with the same virtual and real address spaces.
- Any processor is capable of running any thread in the system.
- Any processor can handle any external interrupt. Each processor handles the internal interrupts generated by the instruction stream it is executing.
- Any processor can initiate an I/O operation.

With this interchangeability, all of the processors are potentially available to handle whatever needs to be done next. The cost of this flexibility is primarily borne by the hardware and software designers, although symmetry also makes the limits on the multiprocessability of the workload more noticeable.

Multiprocessors

AIX Version 4 supports only symmetrical multiprocessors, one form of which is shown in the following illustration. Different systems may have different cache configurations.

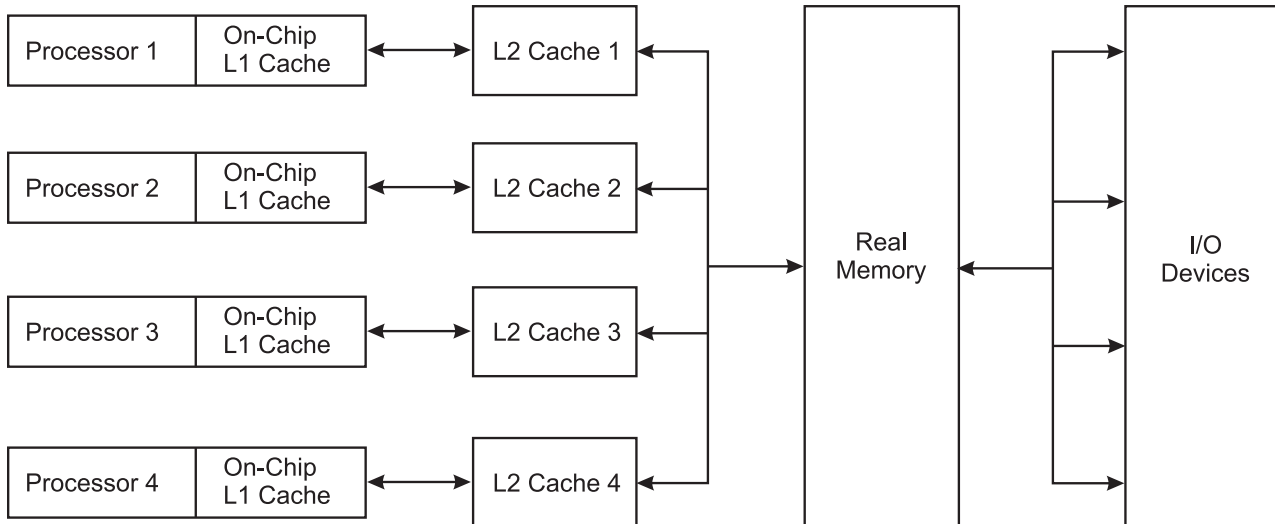

Figure 11. A Typical Symmetrical Multiprocessor System. The illustration shows four boxes representing four individual processors, each with its own on-chip level-one cache. Data is transferred between the L1 cache of the processor, to a separate level-two cache that is assigned to that processor. From the L2 cache, data can be transferred into real memory and back, or sent out to I/O devices for processing.

Although multiprocessor systems are technically symmetrical, a minimal amount of asymmetry is introduced by the software. A single processor is initially in control during the boot process. This first processor to be started is designated as the *master processor*. It is not a master processor in the sense of master/slave processing. The term is only used to designate which processor will be the default processor. The master processor is defined by the value of `MP_MASTER` in the `/usr/include/sys/processor.h` file and is currently 0.

To ensure that user-written software continues to run correctly during the transition from uniprocessor to multiprocessor environments, device drivers and kernel extensions that do not explicitly describe themselves as able to run safely on multiple processors are forced to run only on the master processor. This constraint is called *funneling*.

Parallelizing an Application

An application can be parallelized on an SMP in two ways, as follows:

- The traditional way is to break the application into multiple processes. These processes communicate using inter-process communication (IPC) such as pipes, semaphores or shared memory. The processes must be able to block waiting for events such as messages from other processes, and they must coordinate access to shared objects with something like locks.
- Another way is to use the portable operating system interface for UNIX (POSIX) threads. Threads have similar coordination problems as processes and similar mechanisms to deal with them. Thus a single process can have any number of its threads running simultaneously on different processors. Coordinating them and serializing access to shared data are the developer's responsibility.

Consider the advantages of both threads and processes when you are determining which method to use for parallelizing an application. Threads may be faster than processes and memory sharing is easier. On another hand, a process implementation will distribute more easily to multiple machines or clusters. If an application needs to create or delete new instances, then threads are faster (more overhead in forking processes). For other functions, the overhead of threads is about the same as that of processes.

Data Serialization

Any storage element that can be read or written by more than one thread may change while the program is running. This is generally true of multiprogramming environments as well as multiprocessing environments, but the advent of multiprocessors adds to the scope and importance of this consideration in two ways:

- Multiprocessors and thread support make it attractive and easier to write applications that share data among threads.
- The kernel can no longer solve the serialization problem simply by disabling interrupts.

Note: To avoid serious problems, programs that share data must arrange to access that data serially, rather than in parallel. Before a program updates a shared data item, it must ensure that no other program (including another copy of itself running on another thread) will change the item. Reads can usually be done in parallel.

The primary mechanism that is used to keep programs from interfering with one another is the *lock*. A lock is an abstraction that represents permission to access one or more data items. Lock and unlock requests are atomic; that is, they are implemented in such a way that neither interrupts nor multiprocessor access affect the outcome. All programs that access a shared data item must obtain the lock that corresponds to that data item before manipulating it. If the lock is already held by another program (or another thread running the same program), the requesting program must defer its access until the lock becomes available.

Besides the time spent waiting for the lock, serialization adds to the number of times a thread becomes nondispatchable. While the thread is nondispatchable, other threads are probably causing the nondispatchable thread's cache lines to be replaced, which results in increased memory-latency costs when the thread finally gets the lock and is dispatched.

The operating system's kernel contains many shared data items, so it must perform serialization internally. Serialization delays can therefore occur even in an application program that does not share data with other programs, because the kernel services used by the program have to serialize shared kernel data.

Types of Locks

The Open Software Foundation/1 (OSF/1) 1.1 locking methodology was used as a model for the AIX Version 4 multiprocessor lock functions. However, because the system is preemptable and pageable, some characteristics have been added to the OSF/1 1.1 Locking Model. Simple locks and complex locks are preemptable. Also, a thread may sleep when trying to acquire a busy simple lock if the owner of the lock is not currently running. In addition, a simple lock transforms when a processor has been spinning on a lock for a certain amount of time (this amount of time is a systemwide variable).

AIX Version 4 Simple Locks

A simple lock in operating system version 4 is a spin lock that will sleep under certain conditions preventing a thread from spinning indefinitely. Simple locks are preemptable, meaning that a kernel thread can be preempted by another higher priority kernel thread while it holds a simple lock. On a multiprocessor system, simple locks, which protect thread-interrupt critical sections, must be used in conjunction with interrupt control in order to serialize execution both within the executing processor and between different processors.

On a uniprocessor system, interrupt control is sufficient; there is no need to use locks. Simple locks are intended to protect thread-thread and thread-interrupt critical sections. Simple locks will spin until the lock becomes available if in an interrupt handler. They have two states: locked or unlocked.

AIX Version 4 Complex Locks

The complex locks in AIX Version 4 are read-write locks which protect thread-thread critical sections. These locks are preemptable. Complex locks are spin locks that will sleep under certain conditions. By

default, they are not recursive, but can become recursive through the `lock_set_recursive()` kernel service. They have three states: exclusive-write, shared-read, or unlocked.

Lock Granularity

A programmer working in a multiprocessor environment must decide how many separate locks must be created for shared data. If there is a single lock to serialize the entire set of shared data items, lock contention is comparatively likely. The existence of widely used locks places an upper limit on the throughput of the system.

If each distinct data item has its own lock, the probability of two threads contending for that lock is comparatively low. Each additional lock and unlock call costs processor time, however, and the existence of multiple locks makes a deadlock possible. At its simplest, deadlock is the situation shown in the following illustration, in which Thread 1 owns Lock A and is waiting for Lock B. Meanwhile, Thread 2 owns Lock B and is waiting for Lock A. Neither program will ever reach the `unlock()` call that would break the deadlock. The usual preventive for deadlock is to establish a protocol by which all of the programs that use a given set of locks must always acquire them in exactly the same sequence.

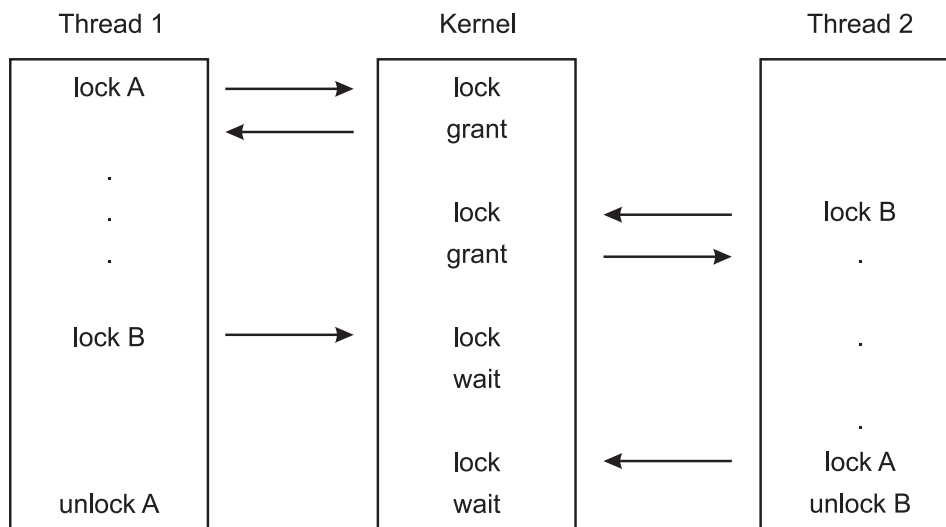

Figure 12. Deadlock. Shown in the following illustration is a deadlock in which a column named Thread 1 owns Lock A and is waiting for Lock B. Meanwhile, the column named Thread 2 owns Lock B and is waiting for Lock A. Neither program thread will ever reach the unlock call that would break the deadlock.

According to queuing theory, the less idle a resource, the longer the average wait to get it. The relationship is nonlinear; if the lock is doubled, the average wait time for that lock more than doubles.

The most effective way to reduce wait time for a lock is to reduce the size of what the lock is protecting. Here are some guidelines:

- Reduce the frequency with which any lock is requested.
- Lock just the code that accesses shared data, not all the code in a component (this will reduce lock holding time).
- Lock only specific data items or structures and not entire routines.
- Always associate locks with specific data items or structures, not with routines.
- For large data structures, choose one lock for each element of the structure rather than one lock for the whole structure.
- Never perform synchronous I/O or any other blocking activity while holding a lock.
- If you have more than one access to the same data in your component, try to move them together so they can be covered by one lock-unlock action.

- Avoid double wake-up. If you modify some data under a lock and have to notify someone that you have done it, release the lock before you post the wake-up.
- If you must hold two locks simultaneously, request the busiest one last.

On the other hand, a too-fine granularity will increase the frequency of locks requests and locks releases, which therefore will add additional instructions. You must locate a balance between a too-fine and too-coarse granularity. The optimum granularity will have to be found by trial and error, and is one of the big challenges in an MP system. The following graph shows the relation between the throughput and the granularity of locks.

Figure 13. Relationship Between Throughput and Granularity. This illustration is a simple two axis chart. The vertical, or y axis, represents throughput. The horizontal, or x axis, represents granularity going from fine to coarse as it moves out on the scale. An elongated bell curve shows the relationship of granularity on throughput. As granularity goes from fine to coarse, throughput gradually increases to a maximum level and then slowly starts to decline. It shows that a compromise in granularity is necessary to reach maximum throughput.

Locking Overhead

Requesting locks, waiting for locks, and releasing locks add processing overhead in several ways:

- A program that supports multiprocessing always does the same lock and unlock processing, even though it is running in a uniprocessor or is the only user in a multiprocessor system of the locks in question.
- When one thread requests a lock held by another thread, the requesting thread may spin for a while or be put to sleep and, if possible, another thread dispatched. This consumes processor time.
- The existence of widely used locks places an upper bound on the throughput of the system. For example, if a given program spends 20 percent of its execution time holding a mutual-exclusion lock, at most five instances of that program can run simultaneously, regardless of the number of processors in the system. In fact, even five instances would probably never be so nicely synchronized as to avoid waiting for one another (see Multiprocessor Throughput Scalability).

Waiting for Locks

When a thread wants a lock already owned by another thread, the thread is blocked and must wait until the lock becomes free. There are two different ways of waiting:

- Spin locks are suitable for locks that are held only for very short times. It allows the waiting thread to keep its processor, repeatedly checking the lock bit in a tight loop (spin) until the lock becomes free. Spinning results in increased CPU time (system time for kernel or kernel extension locks).
- Sleeping locks are suitable for locks that may be held for longer periods. The thread sleeps until the lock is free and is put back in the run queue when the lock becomes free. Sleeping results in more idle time.

Waiting always decreases system performance. If a spin lock is used, the processor is busy, but it is not doing useful work (not contributing to throughput). If a sleeping lock is used, the overhead of context switching and dispatching as well as the consequent increase in cache misses is incurred.

Operating system developers can choose between two types of locks: mutually exclusive simple locks that allow the process to spin and sleep while waiting for the lock to become available, and complex read-write locks that can spin and block the process while waiting for the lock to become available.

Conventions govern the rules about using locks. Neither hardware nor software has an enforcement or checking mechanism. Although using locks has made the AIX Version 4 "MP Safe," developers are responsible to define and implement an appropriate locking strategy to protect their own global data.

Cache Coherency

In designing a multiprocessor, engineers give considerable attention to ensuring cache coherency. They succeed; but cache coherency has a performance cost. We need to understand the problem being attacked:

If each processor has a cache that reflects the state of various parts of memory, it is possible that two or more caches may have copies of the same line. It is also possible that a given line may contain more than one lockable data item. If two threads make appropriately serialized changes to those data items, the result could be that both caches end up with different, incorrect versions of the line of memory. In other words, the system's state is no longer coherent because the system contains two different versions of what is supposed to be the content of a specific area of memory.

The solutions to the cache coherency problem usually include invalidating all but one of the duplicate lines. Although the hardware uses snooping logic to invalidate, without any software intervention, any processor whose cache line has been invalidated will have a cache miss, with its attendant delay, the next time that line is addressed.

Snooping is the logic used to resolve the problem of cache consistency. Snooping logic in the processor broadcasts a message over the bus each time a word in its cache has been modified. The snooping logic also snoops on the bus looking for such messages from other processors.

When a processor detects that another processor has changed a value at an address existing in its own cache, the snooping logic invalidates that entry in its cache. This is called *cross invalidate*. *Cross invalidate* reminds the processor that the value in the cache is not valid, and it must look for the correct value somewhere else (memory or other cache). Since cross invalidates increase cache misses and the snooping protocol adds to the bus traffic, solving the cache consistency problem reduces the performance and scalability of all SMPs.

Processor Affinity and Binding

If a thread is interrupted and later redispached to the same processor, the processor's cache might still contain lines that belong to the thread. If the thread is dispatched to a different processor, it will probably experience a series of cache misses until its cache working set has been retrieved from RAM or the other processor's cache. On the other hand, if a dispatchable thread has to wait until the processor that it was previously running on is available, the thread may experience an even longer delay.

Processor affinity is the probability of dispatching of a thread to the processor that was previously executing it. The degree of emphasis on processor affinity should vary directly with the size of the thread's cache working set and inversely with the length of time since it was last dispatched. The AIX Version 4 dispatcher enforces affinity with the processors, so affinity is done implicitly by the operating system.

The highest possible degree of processor affinity is to bind a thread to a specific processor. Binding means that the thread will be dispatched to that processor only, regardless of the availability of other processors. The **bindprocessor** command and the **bindprocessor()** subroutine bind the thread (or threads) of a specified process to a particular processor (see The *bindprocessor* Command). Explicit binding is inherited through **fork()** and **exec()** system calls.

The binding can be useful for CPU-intensive programs that experience few interrupts. It can sometimes be counterproductive for ordinary programs, because it may delay the redispach of a thread after an I/O until the processor to which the thread is bound becomes available. If the thread has been blocked for the duration of an I/O operation, it is unlikely that much of its processing context remains in the caches of the processor to which it is bound. The thread would probably be better served if it were dispatched to the next available processor.

Memory and Bus Contention

In a uniprocessor, contention for some internal resources, such as banks of memory and I/O or memory buses, is usually a minor component using time. In a multiprocessor, these effects can become more significant, particularly if cache-coherency algorithms add to the number of accesses to RAM.

SMP Performance Issues

To effectively use an SMP, take the following into account when you are attempting to enhance performance:

Workload Concurrency

The primary performance issue that is unique to SMP systems is workload concurrency, which can be expressed as, "Now that we have n processors, how do we keep them all usefully employed"? If only one processor in a four-way multiprocessor system is doing useful work at any given time, it is no better than a uniprocessor. It could possibly be worse, because of the extra code to avoid interprocessor interference.

Workload concurrency is the complement of serialization. To the extent that the system software or the application workload (or the interaction of the two) require serialization, workload concurrency suffers.

Workload concurrency may also be decreased, more desirably, by increased processor affinity. The improved cache efficiency gained from processor affinity may result in quicker completion of the program. Workload concurrency is reduced (unless there are more dispatchable threads available), but response time is improved.

A component of workload concurrency, *process concurrency*, is the degree to which a multithreaded process has multiple dispatchable threads at all times.

Throughput

The throughput of an SMP system is mainly dependent on:

- A consistently high level of workload concurrency. More dispatchable threads than processors at certain times cannot compensate for idle processors at other times.
- The amount of lock contention.
- The degree of processor affinity.

Response Time

The response time of a particular program in an SMP system is dependent on:

- The process-concurrency level of the program. If the program consistently has two or more dispatchable threads, its response time will probably improve in an SMP environment. If the program consists of a single thread, its response time will be, at best, comparable to that in a uniprocessor of the same speed.
- The amount of lock contention of other instances of the program or with other programs that use the same locks.
- The degree of processor affinity of the program. If each dispatch of the program is to a different processor that has none of the program's cache lines, the program may run more slowly than in a comparable uniprocessor.

SMP Workloads

The effect of additional processors on performance is dominated by certain characteristics of the specific workload being handled. This section discusses those critical characteristics and their effects.

The following terms are used to describe the extent to which an existing program has been modified, or a new program designed, to operate in an SMP environment:

SMP safe

Avoidance in a program of any action, such as unserialized access to shared data, that would cause functional problems in an SMP environment. This term, when used alone, usually refers to a program that has undergone only the minimum changes necessary for correct functioning in an SMP environment.

SMP efficient

Avoidance in a program of any action that would cause functional or performance problems in an SMP environment. A program that is described as SMP-efficient is SMP-safe as well. An SMP-efficient program has usually undergone additional changes to minimize incipient bottlenecks.

SMP exploiting

Adding features to a program that are specifically intended to make effective use of an SMP environment, such as multithreading. A program that is described as SMP-exploiting is generally assumed to be SMP-safe and SMP-efficient as well.

Workload Multiprocessability

Multiprogramming operating systems running heavy workloads on fast computers give our human senses the impression that several things are happening simultaneously. In fact, many demanding workloads do not have large numbers of dispatchable threads at any given instant, even when running on a single-processor system where serialization is less of a problem. Unless there are always at least as many dispatchable threads as there are processors, one or more processors will be idle part of the time.

The number of dispatchable threads is the total number of threads in the system

- Minus the number of threads that are waiting for I/O,
- Minus the number of threads that are waiting for a shared resource,
- Minus the number of threads that are waiting for the results of another thread,
- Minus the number of threads that are sleeping at their own request.

A workload can be said to be multiprocessable to the extent that it presents at all times as many dispatchable threads as there are processors in the system. Note that this does not mean simply an average number of dispatchable threads equal to the processor count. If the number of dispatchable threads is zero half the time and twice the processor count the rest of the time, the average number of dispatchable threads will equal the processor count, but any given processor in the system will be working only half the time.

Increasing the multiprocessability of a workload involves one or both of the following:

- Identifying and resolving any bottlenecks that cause threads to wait
- Increasing the total number of threads in the system

These solutions are not independent. If there is a single, major system bottleneck, increasing the number of threads of the existing workload that pass through the bottleneck will simply increase the proportion of threads waiting. If there is not currently a bottleneck, increasing the number of threads may create one.

Multiprocessor Throughput Scalability

Real workloads do not scale perfectly on an SMP system. Some factors that inhibit perfect scaling are as follows:

- Bus/switch contention increases while the number of processors increases
- Memory contention increases (all the memory is shared by all the processors)
- Increased cost of cache misses as memory gets farther away
- Cache cross-invalidates and reads from another cache to maintain cache coherency
- Increased cache misses because of higher dispatching rates (more processes/threads need to be dispatched on the system)
- Increased cost of synchronization instructions
- Increased cache misses because of larger operating system and application data structures
- Increased operating system and application path lengths for lock-unlock
- Increased operating system and application path lengths waiting for locks

All of these factors contribute to what is called the *scalability* of a workload. Scalability is the degree to which workload throughput benefits from the availability of additional processors. It is usually expressed as the quotient of the throughput of the workload on a multiprocessor divided by the throughput on a comparable uniprocessor. For example, if a uniprocessor achieved 20 requests per second on a given workload and a four-processor system achieved 58 requests per second, the scaling factor would be 2.9. That workload is highly scalable. A workload that consisted exclusively of long-running, compute-intensive programs with negligible I/O or other kernel activity and no shared data might approach a scaling factor of 3.2 to 3.9 on a 4-way system. However, most real-world workloads would not. Because scalability is very difficult to estimate, scalability assumptions should be based on measurements of authentic workloads.

The following figure illustrates the problems of scaling. The workload consists of a series of hypothetical commands. Each command is about one-third normal processing, one-third I/O wait, and one-third processing with a lock held. On the uniprocessor, only one command can actually be processing at a time, regardless of whether the lock is held. In the time interval shown (five times the standalone execution time of the command), the uniprocessor handles 7.67 of the commands.

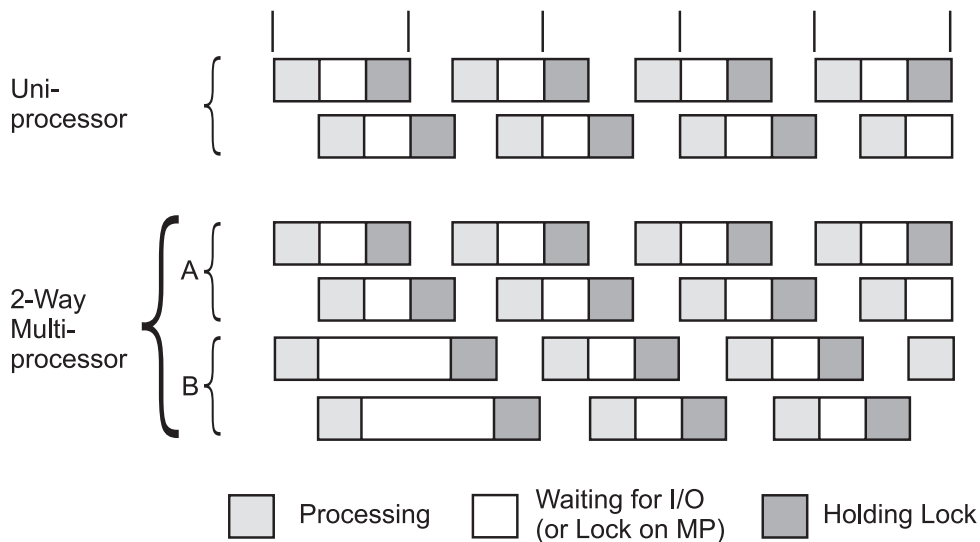

Figure 14. Multiprocessor Scaling. This figure illustrates the problems of scaling. The workload consists of a series of hypothetical commands. Each command is about one-third normal processing, one-third I/O wait, and one-third processing with a lock held. On the uniprocessor, only one command can actually be processing at a time, regardless of whether the lock is held. In the same time interval, the uniprocessor handles 7.67 of the commands. In that same period, the multiprocessor handles 14 commands for a scaling factor of 1.83..

On the multiprocessor, two processors handle program execution, but there is still only one lock. For simplicity, all of the lock contention is shown affecting processor B. In the period shown, the multiprocessor handles 14 commands. The scaling factor is thus 1.83. We stop at two processors because more would not change the situation. The lock is now in use 100 percent of the time. In a four-way multiprocessor, the scaling factor would be 1.83 or less.

Real programs are seldom as symmetrical as the commands in the illustration. In addition we have only taken into account one dimension of contention: locking. If we had included cache-coherency and processor-affinity effects, the scaling factor would almost certainly be lower.

This example illustrates that workloads often cannot be made to run faster simply by adding processors. It is also necessary to identify and minimize the sources of contention among the threads.

Scaling is workload-dependent. Some published benchmark results imply that high levels of scalability are easy to achieve. Most such benchmarks are constructed by running combinations of small, CPU-intensive programs that use almost no kernel services. These benchmark results represent an upper bound on scalability, not a realistic expectation.

Another interesting point to note for benchmarks is that in general, a one-way SMP will run slower (about 5-15 percent) than the equivalent uniprocessor running the UP version of the operating system.

Multiprocessor Response Time

A multiprocessor can only improve the execution time of an individual program to the extent that the program can run in multithreaded mode. There are several ways to achieve parallel execution of parts of a single program:

- Making explicit calls to **libpthreads.a** subroutines (or, in older programs, to the **fork()** subroutine) to create multiple threads that run simultaneously.
- Processing the program with a parallelizing compiler or preprocessor that detects sequences of code that can be executed simultaneously and generates multiple threads to run them in parallel.
- Using a software package that is itself multithreaded.

Unless one or more of these techniques is used, the program will run no faster in a multiprocessor system than in a comparable uniprocessor. In fact, because it may experience more locking overhead and delays due to being dispatched to different processors at different times, it may be slower.

Even if all of the applicable techniques are exploited, the maximum improvement is limited by a rule that has been called Amdahl's Law:

- If a fraction x of a program's uniprocessor execution time, t , can only be processed sequentially, the improvement in execution time in an n -way multiprocessor over execution time in a comparable uniprocessor (the speed-up) is given by the equation:

$$\text{speed up} = \frac{\text{uniprocessor time}}{\text{seq time} + \text{mp time}} = \frac{t}{xt + \frac{(x-1)t}{n}} = \frac{1}{x + \frac{x}{n}}$$

$$\lim_{n \rightarrow \infty} \text{speed-up} = \frac{1}{x}$$

Figure 15. Amdahl's Law. Amdahl's Law says speed-up equals uniprocessor time divided by sequence time plus multiprocessor time or 1 divided by x plus $(x$ over n). Lim speed-up equals 1 divided by x and n equals infinity.

As an example, if 50 percent of a program's processing must be done sequentially, and 50 percent can be done in parallel, the maximum response-time improvement is less than a factor of 2 (in an otherwise-idle 4-way multiprocessor, it is at most 1.6).

SMP Thread Scheduling

Thread support, added to AIX Version 4, divides program-execution control into two elements:

- A *process* is a collection of physical resources required to run the program, such as memory and access to files.
- A *thread* is the execution state of an instance of the program, such as the current contents of the instruction-address register and the general-purpose registers. Each thread runs within the context of a given process and uses that process's resources. Multiple threads can run within a single process, sharing its resources.

In AIX Version 4, the scheduler dispatches threads.

In the SMP environment, the availability of thread support makes it easier and less expensive to implement SMP-exploiting applications. Forking multiple processes to create multiple flows of control is cumbersome and expensive, because each process has its own set of memory resources and requires considerable system processing to set up. Creating multiple threads within a single process requires less processing and uses less memory.

Thread support exists at two levels:

- **libpthreads.a** support in the application program environment
- Kernel thread support

Default Scheduler Processing of Migrated Workloads

The division between processes and threads is invisible to existing programs. In fact, workloads migrated directly from earlier releases of the operating system create processes as they have always done. Each new process is created with a single thread (the initial thread) that contends for the CPU with the threads of other processes.

The default attributes of the initial thread, in conjunction with the new scheduler algorithms, minimize changes in system dynamics for unchanged workloads.

Priorities can be manipulated with the **nice** and **renice** commands and the **setpri()** and **setpriority()** system calls, as before. The scheduler allows a given thread to run for at most one time slice (normally 10 ms) before forcing it to yield to the next dispatchable thread of the same or higher priority. See Controlling Contention for the CPU for more detail.

Scheduling Algorithm Variables

Several variables affect the scheduling of threads. Some are unique to thread support; others are elaborations of process-scheduling considerations:

Priority

A thread's priority value is the basic indicator of its precedence in the contention for processor time.

Scheduler run queue position

A thread's position in the scheduler's queue of dispatchable threads reflects a number of preceding conditions.

Scheduling policy

This thread attribute determines what happens to a running thread at the end of the time slice.

Contention scope

A thread's contention scope determines whether it competes only with the other threads within its process or with all threads in the system. A pthread created with process contention scope is scheduled by the library, while those created with system scope are scheduled by the kernel. The library scheduler utilizes a pool of kernel threads to schedule pthreads with process scope. Generally, create pthreads with system scope, if they are performing I/O. Process scope is useful, when there is a lot of intra-process synchronizations. Contention scope is a **libpthread.a** concept.

Processor affinity

The degree to which affinity is enforced affects performance.

The combinations of these considerations can seem complex, but you can choose from three distinct approaches when you are managing a given process:

Default

The process has one thread, whose priority varies with CPU consumption and whose scheduling policy is SCHED_OTHER.

Process-level control

The process can have one or more threads, but the scheduling policy of those threads is left as the default SCHED_OTHER, which permits the use of the existing methods of controlling nice values and fixed priorities. All of these methods affect all of the threads in the process identically. If the **setpri()** subroutine is used, the scheduling policy of all of the threads in the process is set to SCHED_RR.

Thread-level control

The process can have one or more threads. The scheduling policy of these threads is set to SCHED_RR or SCHED_FIFO, as appropriate. The priority of each thread is fixed and is manipulated with thread-level subroutines.

The scheduling policies are described in Scheduling Policy for Threads.

Thread Tuning

User threads provide independent flow of control within a process. If the user threads need to access kernel services (such as system calls), the user threads will be serviced by associated kernel threads. User threads are provided in various software packages with the most notable being the pthreads shared library (**libpthreads.a**). With the libpthreads implementation, user threads sit on top of virtual processors (VP) which are themselves on top of kernel threads. A multithreaded user process can use one of two models, as follows:

- **1:1 Thread Model**

The 1:1 model indicates that each user thread will have exactly one kernel thread mapped to it. This is the default model on AIX 4.1, AIX 4.2, and AIX 4.3. In this model, each user thread is bound to a VP and linked to exactly one kernel thread. The VP is not necessarily bound to a real CPU (unless binding to a processor was done). A thread which is bound to a VP is said to have system scope because it is directly scheduled with all the other user threads by the kernel scheduler.

- **M:N Thread Model**

The M:N model was implemented in AIX 4.3.1 and is also now the default model. In this model, several user threads can share the same virtual processor or the same pool of VPs. Each VP can be thought of as a virtual CPU available for executing user code and system calls. A thread which is not bound to a VP is said to be a local or process scope because it is not directly scheduled with all the other threads by the kernel scheduler. The pthreads library will handle the scheduling of user threads to the VP and then the kernel will schedule the associated kernel thread. As of AIX 4.3.2, the default is to have one kernel thread mapped to eight user threads. This is tunable from within the application or through an environment variable.

Thread Environment Variables

Within the **libpthreads.a** framework, a series of tuning knobs have been provided that might impact the performance of the application. If possible, the application developer should provide a front-end shell script to invoke the binary executable programs, in which the developer may specify new values to override the system defaults. These environment variables are as follows:

SPINLOOPTIME=*n*

Controls the number of times that the system will try to get a busy mutex or spin lock without taking a secondary action such as calling the kernel to yield the process. This control is intended for MP systems, where it is hoped that the lock being held by another actively running pthread will be released. The parameter works only within libpthreads (user threads). The kernel parameter **MAXSPIN** affects spinning in the kernel lock routines (see The schedtune -s Command). If locks are usually available within a short amount of time, you may want to increase the spin time by setting this environment variable. The number of times to retry a busy lock before yielding to another pthread is *n*. The default is 40 and *n* must be a positive value.

YIELDLOOPTIME=*n*

Controls the number of times that the system yields the processor when trying to acquire a busy mutex or spin lock before actually going to sleep on the lock. The processor is yielded to another kernel thread, assuming there is another runnable one with sufficient priority. This variable has been shown to be effective in complex applications, where multiple locks are in use. The number of times to yield the processor before blocking on a busy lock is *n*. The default is 0 and *n* must be a positive value.

AIXTHREAD_SCOPE={*PIS*}

P signifies process-wide contention scope (M:N) and *S* signifies system-wide contention scope (1:1). Either *P* or *S* should be specified and the current default is process-wide scope.

The use of this environment variable impacts only those threads created with the default attribute. The default attribute is employed, when the *attr* parameter to the **pthread_create()** subroutine is NULL.

If a user thread is created with system-wide scope, it is bound to a kernel thread and it is scheduled by the kernel. The underlying kernel thread is not shared with any other user thread.

If a user thread is created with process-wide scope, it is subject to the user scheduler. It does not have a dedicated kernel thread; it sleeps in user mode; it is placed on the user run queue when it is waiting for a processor; and it is subjected to time slicing by the user scheduler.

Tests on AIX 4.3.2 have shown that certain applications can perform much better with the 1:1 model.

AIXTHREAD_GUARDPAGES=*n*

The decimal number of guard pages to add to the end of the pthread stack is *n*. It overrides the attribute values that are specified at pthread creation time. If the application specifies its own stack, no guard pages are created. The default is 0 and *n* must be a positive value.

MALLOCMULTIHEAP={considersize,heaps:*n*}

Multiple heaps are required so that a threaded application can have more than one thread issuing **malloc()**, **free()**, and **realloc()** subroutine calls. With a single heap, all threads trying to do a **malloc()**, **free()**, or **realloc()** call would be serialized (that is only one thread can do malloc/free/realloc at a time). The result is a serious impact on multi-processor machines. With multiple heaps, each thread gets its own heap. If all heaps are being used then any new threads trying to malloc/free/realloc will have to wait (that is serialize) until one or more of the heaps becomes available again. We still have serialization, but its likelihood and impact are greatly reduced.

The thread-safe locking has been changed to handle this approach. Each heap has its own lock, and the locking routine "intelligently" selects a heap to try to prevent serialization. If **considersize** is set in the **MALLOCMULTIHEAP** environment variable, then the selection will also try to select any available heap that has enough free space to handle the request instead of just selecting the next unlocked heap.

More than one option can be specified (and in any order) as long as they are comma-separated, for example, **MALLOCMULTIHEAP=considersize,heaps:3**. The options are:

heaps:*n*

The number of heaps used can be changed with this option. If *n* is not valid (that is, $n \leq 0$ or $n > 32$), 32 is used.

considersize

Uses a different heap-selection algorithm that tries to minimize the working set size of the process. The default is not to consider it and use the faster algorithm.

The default for **MALLOCMULTIHEAP** is NOT SET (only the first heap is used). If the environment variable **MALLOCMULTIHEAP** is set (for example, **MALLOCMULTIHEAP=1**) then the threaded application will be able to use all of the 32 heaps. Setting **MALLOCMULTIHEAP=heaps:*n*** will limit the number of heaps to *n* instead of the 32 heaps.

Variables for Process-Wide Contention Scope

The following environment variables impact the scheduling of pthreads created with process-wide contention scope.

AIXTHREAD_MNRATIO=*p:k*

where *k* is the number of kernel threads that should be employed to handle *p* runnable pthreads. This environment variable controls the scaling factor of the library. This ratio is used when creating and terminating pthreads. The variable is only valid with process-wide scope; with system-wide scope, this environment variable is ignored. The default setting is 8:1.

AIXTHREAD_SLPRATIO=*k:p*

where *k* is the number of kernel threads that should be held in reserve for *p* sleeping pthreads. The sleep ratio is the number of kernel threads to keep on the side in support of sleeping pthreads. In general, fewer kernel threads are required to support sleeping pthreads, since they

are generally woken one at a time. This conserves kernel resources. Any positive integer value may be specified for p and k . If $k > p$, then the ratio is treated as 1:1. The default is 1:12.

AIXTHREAD_MINKTHREADS= n

where n is the minimum number of kernel threads that should be used. The library scheduler will not reclaim kernel threads below this figure. A kernel thread may be reclaimed at virtually any point. Generally, a kernel thread is targeted for reclaim as a result of a pthread terminating. The default is 8.

Thread Debug Options

The pthreads library maintains a list of active mutexes, condition variables, and read-write locks for use by the debugger.

When a lock is initialized, it is added to the list, assuming that it is not already on the list. The list is held as a linked list, so determining that a new lock is not already on the list has a performance implication when the list gets large. The problem is compounded by the fact that the list is protected by a lock (`dbx__mutexes`), which is held across the search of the list. In this case other calls to the `pthread_mutex_init()` subroutine are held while the search is done.

If the following environment variables are set to OFF (the default is ON), then the appropriate debugging list will be disabled completely. That means the **dbx** command (or any debugger using the pthread debug library) will show no objects in existence.

- **AIXTHREAD_MUTEX_DEBUG**
- **AIXTHREAD_COND_DEBUG**
- **AIXTHREAD_RWLOCK_DEBUG**

To change any of these environment variables, use the following command:

```
# export variable_name=OFF
```

Thread Tuning Summary

Depending on the type of application, the administrator can choose to use a different thread model. Tests on AIX 4.3.2 have shown that certain applications can perform much better with the 1:1 model. This is an important point because the default as of AIX 4.3.1 is M:N. By simply setting the environment variable **AIXTHREAD_SCOPE=S** for that process, we can set the thread model to 1:1 and then compare the performance to its previous performance when the thread model was M:N.

If you see an application creating and deleting threads, it could be the kernel threads are being *harvested* because of the 8:1 default ratio of user threads to kernel threads. This harvesting along with the overhead of the library scheduling can affect the performance. On the other hand, when thousands of user threads exist, there may be less overhead to schedule them in user space in the library rather than manage thousands of kernel threads. You should always try changing the scope if you encounter a performance problem when using pthreads; in many cases, the system scope can provide better performance.

If an application is running on an SMP system, then if a user thread cannot acquire a mutex, it will attempt to spin for up to 40 times. It could easily be the case that the mutex was available within a short amount of time, so it may be worthwhile to spin for a longer period of time. As you add more CPUs, if the performance goes down, this usually indicates a locking problem. You might want to increase the spin time by setting the environment variable **SPINLOOPTIME= n** , where n is the number of spins. It is not unusual to set the value as high as in the thousands depending on the speed of the CPUs and the number of CPUs. Once the spin count has been exhausted, the thread can go to sleep waiting for the mutex to become available or it can issue the **yield()** system call and simply give up the CPU but stay in a runnable state rather than going to sleep. By default, it will go to sleep, but by setting the **YIELDLOOPTIME** environment variable to a number, it will yield up to that many times before going to sleep. Each time it gets the CPU after it yields, it can try to acquire the mutex.

Certain multithreaded user processes that use the malloc subsystem heavily may obtain better performance by exporting the environment variable **MALLOCMULTIHEAP=1** before starting the application. The potential performance improvement is particularly likely for multithreaded C++ programs, because these may make use of the malloc subsystem whenever a constructor or destructor is called. Any available performance improvement will be most evident when the multithreaded user process is running on an SMP system, and particularly when system scope threads are used (M:N ratio of 1:1). However, in some cases, improvement may also be evident under other conditions, and on uniprocessors.

SMP Tools

All performance tools of the operating system support SMP machines. Some performance tools provide individual processor utilization statistics. Other performance tools average out the utilization statistics for all processors and display only the averages.

This section describes the tools that are only supported on SMP. For details on all other performance tools, see the appropriate chapters.

The `bindprocessor` Command

Use the `bindprocessor` command to bind or unbind the kernel threads of a process to a processor. Root authority is necessary to bind or unbind threads in processes that you do not own.

Note: The `bindprocessor` command is meant for multiprocessor systems. Although it will also work on uniprocessor systems, binding has no effect on such systems.

To query the available processors, run the following:

```
# bindprocessor -q
The available processors are: 0 1 2 3
```

The output shows the logical processor numbers for the available processors, which are used with the `bindprocessor` command as will be seen.

To bind a process whose PID is 14596 to processor 1, run the following:

```
# bindprocessor 14596 1
```

No return message is given if the command was successful. To verify if a process is bound or unbound to a processor, use the `ps -mo THREAD` command as explained in Using the `ps` Command:

```
# ps -mo THREAD
USER  PID  PPID   TID ST  CP  PRI  SC   WCHAN          F    TT  BND  COMMAND
root  3292  7130   -  A   1   60   1    -    240001 pts/0 -  -ksh
-      -      - 14309 S   1   60   1    -     400      -  -  -
root  14596 3292   -  A  73  100   1    -    200001 pts/0 1  /tmp/cpubound
-      -      - 15629 R  73  100   1    -     0        -  1  -
root  15606 3292   -  A  74  101   1    -    200001 pts/0 -  /tmp/cpubound
-      -      - 16895 R  74  101   1    -     0        -  -  -
root  16634 3292   -  A  73  100   1    -    200001 pts/0 -  /tmp/cpubound
-      -      - 15107 R  73  100   1    -     0        -  -  -
root  18048 3292   -  A  14  67   1    -    200001 pts/0 -  ps -mo THREAD
-      -      - 17801 R  14  67   1    -     0        -  -  -
```

The column `BND` shows the number of the processor that the process is bound to or a dash (-) if the process is not bound at all.

To unbind a process whose PID is 14596, use the following command:

```
# bindprocessor -u 14596
# ps -mo THREAD
USER  PID  PPID   TID ST  CP  PRI  SC   WCHAN          F    TT  BND  COMMAND
root  3292  7130   -  A   2   61   1    -    240001 pts/0 -  -ksh
```

```

- - - 14309 S 2 61 1 - 400 - - -
root 14596 3292 - A 120 124 1 - 200001 pts/0 - /tmp/cpubound
- - - 15629 R 120 124 1 - 0 - - -
root 15606 3292 - A 120 124 1 - 200001 pts/0 - /tmp/cpubound
- - - 16895 R 120 124 1 - 0 - - -
root 16634 3292 - A 120 124 0 - 200001 pts/0 - /tmp/cpubound
- - - 15107 R 120 124 0 - 0 - - -
root 18052 3292 - A 12 66 1 - 200001 pts/0 - ps -mo THREAD
- - - 17805 R 12 66 1 - 0 - - -

```

When the **bindprocessor** command is used on a process, all of its threads will then be bound to one processor and unbound from their former processor. Unbinding the process will also unbind all its threads. You cannot bind or unbind an individual thread using the **bindprocessor** command.

However, within a program, you can use the **bindprocessor()** function call to bind individual threads. If the **bindprocessor()** function is used within a piece of code to bind threads to processors, the threads remain with these processors and cannot be unbound. If the **bindprocessor** command is used on that process, all of its threads will then be bound to one processor and unbound from their respective former processors. An unbinding of the whole process will also unbind all the threads.

A process cannot be bound until it is started; that is, it must exist in order to be bound. When a process does not exist, the following error displays:

```

# bindprocessor 7359 1
1730-002: Process 7359 does not match an existing process

```

When a processor does not exist, the following error displays:

```

# bindprocessor 7358 4
1730-001: Processor 4 is not available

```

Note: Do not use the **bindprocessor** command on the wait processes **kproc**.

Considerations

Binding can be useful for CPU-intensive programs that experience few interrupts. It can sometimes be counterproductive for ordinary programs because it may delay the redispach of a thread after an I/O until the processor to which the thread is bound becomes available. If the thread has been blocked for the duration of an I/O operation, it is unlikely that much of its processing context remains in the caches of the processor to which it is bound. The thread would probably be better served if it were dispatched to the next available processor.

Binding does not prevent other processes from being dispatched on the processor on which you bound your process. Binding is different from partitioning. Without Workload Manager (WLM), introduced in AIX 4.3.3, it is not possible to dedicate a set of processors to a specific workload and another set of processors to another workload. Therefore, a higher priority process might be dispatched on the processor where you bound your process. In this case, your process will not be dispatched on other processors, and therefore, you will not always increase the performance of the bound process. Better results may be achieved if you increase the priority of the bound process.

If you bind a process on a heavily loaded system, you might decrease its performance because when a processor becomes idle, the process will not be able to run on the idle processor if it is not the processor on which the process is bound.

If the process is multithreaded, binding the process will bind all its threads to the same processor. Therefore, the process does not take advantage of the multiprocessing, and performance will not be improved.

Note: Use process binding with care, because it disrupts the natural load balancing provided by AIX Version 4, and the overall performance of the system could degrade. If the workload of the machine changes from that which is monitored when making the initial binding, system performance can

suffer. If you use the **bindprocessor** command, take care to monitor the machine regularly because the environment might change, making the bound process adversely affect system performance.

The lockstat Command

The **lockstat** command is only available in AIX Version 4.

As described earlier in this chapter, the use of locks and finding the right granularity is one of the big challenges in a MP operating system. You need to have a way to determine if locks are posing a problem on the system (for example, lock contention). The **lockstat** command displays lock-contention statistics for operating system locks on SMP systems.

To determine whether the **lockstat** command is installed and available, run the following command:

```
# ls1pp -lI perfagent.tools
```

Before you use the **lockstat** command, create as root a new **bosboot** image with the **-L** option to enable lock instrumentation. Assume that the boot disk is `hdisk0`. Run the following:

```
# bosboot -a -d /dev/hdisk0 -L
```

After you run the command, reboot the machine to enable lock instrumentation. At this time, you can use the **lockstat** command to look at the locking activity.

It is only possible to see which kernel locks are generated by the workload. Application locks cannot be seen directly with the **lockstat** command. However, they can be seen indirectly. In that case, check the application for bottlenecks, such as:

- One message queue with lots of processes writing and one reading (VMM)
- All processes yield (Dispatcher)

The **lockstat** command can be CPU-intensive because there is overhead involved with lock instrumentation, which is why it is not turned on by default. The overhead of enabling lock instrumentation is typically 3-5 percent. Also note that trace buffers fill up much quicker when using this option because there are a lot of locks being used.

AIX Version 4 defines subsystems comprised of lock classes in `/usr/include/sys/lockname.h`. Each time an operating system developer needs to acquire a lock, they pick up or create a lock class which serves to identify the lock.

The **lockstat** command generates a report for each kernel lock that meets all specified conditions. When no conditions are specified, the default values are used. The following are the parameters that can be used to filter the data collected:

- a** Displays a supplementary list showing the most requested (or active) locks, regardless of the conditions defined by other flags.
- c LockCount**
Specifies how many times a lock must be requested during an interval in order to be displayed. A lock request is a lock operation which in some cases cannot be satisfied immediately. All lock requests are counted. The default is 200.
- b BlockRatio**
Specifies a block ratio. When a lock request is not satisfied, it is said to be blocked. A lock must have a block ratio that is higher than *BlockRatio* to appear in the list. The default of *BlockRatio* is 5 percent.
- n CheckCount**
Specifies the number of locks that are to be checked. The **lockstat** command sorts locks according to lock activity. This parameter determines how many of the most active locks will be

subject to further checking. Limiting the number of locks that are checked maximizes system performance, particularly if the **lockstat** command is executed in intervals. The default value is 40.

-p LockRate

Specifies a percentage of the activity of the most-requested lock in the kernel. Only locks that are more active than this percentage will be listed. The default value is 2, which means that the only locks listed are those requested at least 2 percent as often as the most active lock.

-t MaxLocks

Specifies the maximum number of locks to be displayed. The default is 10.

If the **lockstat** command is executed with no options, an output similar to the following is displayed:

```
# lockstat
Subsys Name                Ocn  Ref/s  %Ref  %Block %Sleep
-----
PFS   IRDWR_LOCK_CLASS        259  75356  37.49  9.44  0.21
PROC  PROC_INT_CLASS            1    12842  6.39  17.75  0.00
```

The first column is the subsystem (Subsys) to which the lock belongs. Some common subsystems are as follows:

- PROC** Scheduler, dispatcher or interrupt handlers
- VMM** Pages, segment and free list
- TCP** Sockets, NFS
- PFS** I-nodes, i-cache

Next, the symbolic name of the lock class is shown. Some common classes are as follows:

- TOD_LOCK_CLASS**
All interrupts that need the Time-of-Day (TOD) timer
- PROC_INT_CLASS**
Interrupts for processes
- U_TIMER_CLASS**
Per-process timer lock
- VMM_LOCK_VMKER**
Free list
- VMM_LOCK_PDT**
Paging device table
- VMM_LOCK_LV**
Per paging space
- ICACHE_LOCK_CLASS**
I-node cache

The other columns are as follows:

- The **Ocn** column provides the occurrence number of the lock in its class.
- The reference number (**Ref/s**) is the number of lock requests per second.
- The **%Ref** column is the reference rate expressed as a percentage of all lock requests.
- The last two columns present respectively the ratio of blocking lock requests to total lock requests (**%Block**) and the percentage of lock requests that cause the calling thread to sleep (**%Sleep**).

As a guideline, be concerned if a lock has a reference number (**Ref/s**) above 10000. In the example, both classes shown present a very high rate. In this case, you may want to use the **vmstat** command to

investigate further. Refer to The `vmstat` Command for more information. If the output of the `vmstat` command shows a significant amount of CPU idle time when the system seems subjectively to be running slowly, delays might be due to kernel lock contention, because lock requestors go into blocked mode. Lock contentions cause wasted cycles because a thread may be spinning on a busy lock or sleeping until the lock is granted. Improper designs may even lead to deadlocks. The wasted cycles would degrade system performance.

The `lockstat` command output does not indicate exactly which application is causing a problem to the system. The lock-contentions problem can only be solved at the source-code level. For example, if your application has a high number of processes that read and write a unique message queue, you might have lock contention for the inter-process communication (IPC) subsystem. Adding more message queues may reduce the level of lock contention.

In this example, many instances of a process that opens the same file for read-only were running simultaneously on the system. In the operating system, every time a file is accessed, its i-node is updated with the last access time. That is the reason for the high reference number observed for the lock class `IRDWR_LOCK_CLASS`. Many threads were trying to update the i-node of the same file concurrently.

When the `lockstat` command is run without options, only the locks with `%Block` above 5 percent are listed. You can change this behavior by specifying another `BlockRatio` with the `-b` option, as follows:

```
# lockstat -b 1
Subsys Name                Ocn  Ref/s  %Ref  %Block %Sleep
-----
PFS    IRDWR_LOCK_CLASS        258  95660  60.22  69.15  0.16
PROC   PROC_INT_CLASS           1    5798   3.65   4.73   0.00
PROC   PROC_INT_CLASS           2    2359   1.48   1.02   0.00
```

In this case, all the lock requests with `%Block` above 1 percent will be shown.

If no lock has a `BlockRatio` within the given range, the output would be as follows:

```
# lockstat
No Contention
```

However, this might also indicate that the lock instrumentation has not been activated.

The `-a` option additionally lists the 10 most-requested (or active) locks, as follows:

```
# lockstat -a
Subsys Name                Ocn  Ref/s  %Ref  %Block %Sleep
-----
PFS    IRDWR_LOCK_CLASS        259  75356  37.49   9.44   0.21
PROC   PROC_INT_CLASS           1   12842   6.39  17.75   0.00
```

First 10 largest reference rate locks :

```
Subsys Name                Ocn  Ref/s  %Ref  %Block %Sleep
-----
PFS    IRDWR_LOCK_CLASS        259  75356  37.49   9.44   0.21
PROC   PROC_INT_CLASS           1   12842   6.39  17.75   0.00
PROC   TOD_LOCK_CLASS          --   5949   2.96   1.68   0.00
PROC   PROC_INT_CLASS           2   5288   2.63   3.97   0.00
XPSE   PSE_OPEN_LOCK           --   4498   2.24   0.87   0.00
IOS    SELPOLL_LOCK_CLASS      --   4276   2.13   3.20   0.00
XPSE   PSE_SQH_LOCK            95   4223   2.10   0.62   0.00
XPSE   PSE_SQH_LOCK           105   4213   2.10   0.50   0.00
XPSE   PSE_SQH_LOCK            75   3585   1.78   0.31   0.00
XPTY   PTY_LOCK_CLASS           6    3336   1.66   0.00   0.00
```

The meaning of the fields is the same as in the previous example. The first table is a list of locks with %Block above 5 percent. A list of the top 10 reference-rate locks, sorted in decreasing order, is then provided. The number of locks in the most-requested list can be changed with the **-t** option, as follows:

```
# lockstat -a -t 3
Subsys Name                Ocn  Ref/s  %Ref  %Block %Sleep
-----
PFS   IRDWR_LOCK_CLASS       259  75356  37.49  9.44  0.21
PROC  PROC_INT_CLASS           1   12842  6.39  17.75  0.00
```

First 3 largest reference rate locks :

```
Subsys Name                Ocn  Ref/s  %Ref  %Block %Sleep
-----
PFS   IRDWR_LOCK_CLASS       259  75356  37.49  9.44  0.21
PROC  PROC_INT_CLASS           1   12842  6.39  17.75  0.00
PROC  TOD_LOCK_CLASS         --    5949  2.96  1.68  0.00
```

In the previous example, the **-t** option specifies that only the top three reference-rate locks will be shown.

If the output of the **lockstat -a** command looks similar to the following:

```
No Contention
```

First 10 largest reference rate locks :

```
Subsys Name                Ocn  Ref/s  %Ref  %Block %Sleep
-----
```

then an empty most-requested lock list means that the lock instrumentation has not been enabled. It can be enabled by executing the **bosboot** command as explained at the beginning of this section.

The **lockstat** command can also be run in intervals, as follows:

```
# lockstat 10 100
```

The first number passed in the command line specifies the amount of time (in seconds) between each report. Each report contains statistics collected during the interval since the previous report. If no interval is specified, the system gives information covering an interval of one second and then exits. The second number determines the number of reports generated. The second number can only be specified if an interval is given.

Note: Under excessive lock contention on large SMPs, the **lockstat** command does not scale well and might not return in the time period specified.

The schedtune -s Command

If a thread wants to acquire a lock when another thread currently owns that lock and is running on another CPU, the thread that wants the lock will spin on the CPU until the owner thread releases the lock. Prior to AIX 4.3.1, this thread would spin indefinitely. In AIX 4.3.1, the thread spins up to a certain value as specified by a tunable parameter called **MAXSPIN**.

The default value of **MAXSPIN** was previously 0xFFFFFFFF (the hexadecimal representation of a very large number in decimal form) on SMP systems and 1 on UP systems. In AIX 4.3.1, the default value of **MAXSPIN** is 0x4000 (16384) for SMP systems and remains at 1 on UP systems. If you notice more idle or I/O wait time on a system that had not shown this previously, it could be that threads are going to sleep more often. If this is causing a performance problem, then tune **MAXSPIN** such that it is a higher value or set to -1 which means to spin up to 0xFFFFFFFF times.

To revise the number of times to spin before going to sleep use the **-s** option of the **schedtune** command. To reduce CPU usage that might be caused by excessive spins, reduce the value of **MAXSPIN** as follows:

```
# /usr/samples/kernel/schedtune -s 8192
```

You may observe an increase in context-switching. If context-switching becomes the bottleneck, increase **MAXSPIN**.

To determine whether the **schedtune** command is installed and available, run the following command:

```
# ls1pp -lI bos.adt.samples
```

To change the value, you must be the root user.

Chapter 4. Planning and Implementing for Performance

A program that does not perform acceptably is not functional. Every program must satisfy a set of users, sometimes a large and diverse set. If the performance of the program is truly unacceptable to a significant number of those users, it will not be used. A program that is not being used is not performing its intended function.

This situation is true of licensed software packages as well as user-written applications, although most developers of software packages are aware of the effects of poor performance and take pains to make their programs run as fast as possible. Unfortunately, they cannot anticipate all of the environments and uses that their programs will experience. Final responsibility for acceptable performance falls on the people who select or write, plan for, and install software packages.

This chapter describes the stages by which a programmer or system administrator can ensure that a newly written or purchased program has acceptable performance. (Wherever the word *programmer* appears alone, the term includes system administrators and anyone else who is responsible for the ultimate success of a program.)

To achieve acceptable performance in a program, identify and quantify acceptability at the start of the project and never lose sight of the measures and resources needed to achieve it. Although this method sounds elementary, some programming projects consciously reject it. They adopt a policy that might be fairly described as design, code, debug, maybe document, and if we have time, fix the performance.

The only way that programs can predictably be made to function in time, not just in logic, is by integrating performance considerations in the software planning and development process. Advance planning is perhaps more critical when existing software is being installed, because the installer has less freedom than the developer.

Although the detail of this process might seem burdensome for a small program, remember that we have a second "agenda." Not only must the new program have satisfactory performance, we must also ensure that the addition of that program to an existing system does not degrade the performance of other programs run on that system.

This chapter includes the following major sections:

- Identifying the Components of the Workload
- Documenting Performance Requirements
- Estimating the Resource Requirements of the Workload
- Designing and Implementing Efficient Programs
- Using Performance-Related Installation Guidelines

Identifying the Components of the Workload

Whether the program is new or purchased, small or large, the developers, the installers, and the prospective users have assumptions about the use of the program, such as:

- Who will be using the program
- Situations in which the program will be run
- How often those situations will arise and at what times of the hour, day, month, or year
- Whether those situations will also require additional uses of existing programs
- Which systems the program will run on
- How much data will be handled, and from where
- Whether data created by or for the program will be used in other ways

Unless these ideas are elicited as part of the design process, they will probably be vague, and the programmers will almost certainly have different assumptions than the prospective users. Even in the apparently trivial case in which the programmer is also the user, leaving the assumptions unarticulated makes it impossible to compare design to assumptions in any rigorous way. Worse, it is impossible to identify performance requirements without a complete understanding of the work being performed.

Documenting Performance Requirements

In identifying and quantifying performance requirements, it is important to identify the reasoning behind a particular requirement. This is part of the general capacity planning process. Users might be basing their statements of requirements on assumptions about the logic of the program that do not match the programmer's assumptions. At a minimum, a set of performance requirements should document the following:

- The maximum satisfactory response time to be experienced most of the time for each distinct type of user-computer interaction, along with a definition of *most of the time*. Response time is measured from the time that the user performs the action that says "Go" until the user receives enough feedback from the computer to continue the task. It is the user's subjective wait time. It is not from entry to a subroutine until the first write statement.

If the user denies interest in response time and indicates that only the result is of interest, you can ask whether "ten times your current estimate of stand-alone execution time" would be acceptable. If the answer is "yes," you can proceed to discuss throughput. Otherwise, you can continue the discussion of response time with the user's full attention.

- The response time that is minimally acceptable the rest of the time. A longer response time can cause users to think the system is down. You also need to specify *rest of the time*; for example, the peak minute of a day, 1 percent of interactions. Response time degradations can be more costly or painful at a particular time of the day.
- The typical throughput required and the times it will be taking place. This is not a casual consideration. For example, the requirement for one program might be that it runs twice a day: at 10:00 a.m. and 3:15 p.m. If this is a CPU-limited program that runs for 15 minutes and is planned to run on a multiuser system, some negotiation is in order.
- The size and timing of maximum-throughput periods.
- The mix of requests expected and how the mix varies with time.
- The number of users per machine and total number of users, if this is a multiuser application. This description should include the times these users log on and off, as well as their assumed rates of keystrokes, completed requests, and think times. You may want to investigate whether think times vary systematically with the preceding and following request.
- Any assumptions that the user is making about the machines the workload will run on. If the user has a specific existing machine in mind, make sure you know that early on. Similarly, if the user is assuming a particular type, size, cost, location, interconnection, or any other variable that will constrain your ability to satisfy the preceding requirements, that assumption also becomes part of the requirements. Satisfaction will probably not be assessed on the system where the program is developed, tested, or first installed.

Estimating the Resource Requirements of the Workload

Unless you are purchasing a software package that comes with detailed resource-requirement documentation, estimating resources can be the most difficult task in the performance-planning process. The difficulty has several causes, as follows:

- There are several ways to do any task. You can write a C (or other high-level language) program, a shell script, a **perl** script, an **awk** script, a **sed** script, an AIXwindows dialog, and so on. Some techniques that may seem particularly suitable for the algorithm and for programmer productivity are extraordinarily expensive from the performance perspective.

A useful guideline is that, the higher the level of abstraction, the more caution is needed to ensure that one does not receive a performance surprise. Consider carefully the data volumes and number of iterations implied by some apparently harmless constructs.

- The precise cost of a single process is difficult to define. This difficulty is not merely technical; it is philosophical. If multiple instances of a given program run by multiple users are sharing pages of program text, which process should be charged with those pages of memory? The operating system leaves recently used file pages in memory to provide a caching effect for programs that reaccess that data. Should programs that reaccess data be charged for the space that was used to retain the data? The granularity of some measurements such as the system clock can cause variations in the CPU time attributed to successive instances of the same program.

Two approaches deal with resource-report ambiguity and variability. The first is to ignore the ambiguity and to keep eliminating sources of variability until the measurements become acceptably consistent. The second approach is to try to make the measurements as realistic as possible and describe the results statistically. Note that the latter yields results that have some correlation with production situations.

- Systems are rarely dedicated to running a single instance of a single program. There are almost always daemons running, there is frequently communications activity, and often workload from multiple users. These activities seldom add up linearly. For example, increasing the number of instances of a given program may result in few new program text pages being used, because most of the program was already in memory. However, the additional processes may result in more contention for the processor's caches, so that not only do the other processes have to share processor time with the newcomer, but all processes may experience more cycles per instruction. This is, in effect, a slowdown of the processor, as a result of more frequent cache misses.

Make your estimate as realistic as the specific situation allows, using the following guidelines:

- If the program exists, measure the existing installation that most closely resembles your own requirements. The best method is to use a capacity planning tool such as BEST/1.
- If no suitable installation is available, do a trial installation and measure a synthetic workload.
- If it is impractical to generate a synthetic workload that matches the requirements, measure individual interactions and use the results as input to a simulation.
- If the program does not exist yet, find a comparable program that uses the same language and general structure, and measure it. Again, the more abstract the language, the more care is needed in determining comparability.
- If no comparable program exists, develop a prototype of the main algorithms in the planned language, measure the prototype, and model the workload.
- Only if measurement of any kind is impossible or infeasible should you make an educated guess. If it is necessary to guess at resource requirements during the planning stage, it is critical that the actual program be measured at the earliest possible stage of its development.

Keep in mind that independent software vendors (ISV) often have sizing guidelines for their applications.

In estimating resources, we are primarily interested in four dimensions (in no particular order):

CPU time

Processor cost of the workload

Disk accesses

Rate at which the workload generates disk reads or writes

LAN traffic

Number of packets the workload generates and the number of bytes of data exchanged

Real memory

Amount of RAM the workload requires

The following sections discuss how to determine these values in various situations.

Measuring Workload Resources

If the real program, a comparable program, or a prototype is available for measurement, the choice of technique depends on the following:

- Whether the system is processing other work in addition to the workload we want to measure.
- Whether we have permission to use tools that may degrade performance (for example, is this system in production or is it dedicated to our use for the duration of the measurement?).
- The degree to which we can simulate or observe an authentic workload.

Measuring a Complete Workload on a Dedicated System

Using a dedicated system is the ideal situation because we can use measurements that include system overhead as well as the cost of individual processes.

To measure overall system performance for most of the system activity, use the **vmstat** command:

```
# vmstat 5 >vmstat.output
```

This gives us a picture of the state of the system every 5 seconds during the measurement run. The first set of **vmstat** output contains the cumulative data from the last boot to the start of the **vmstat** command. The remaining sets are the results for the preceding interval, in this case 5 seconds. A typical set of **vmstat** output on a system looks similar to the following:

```
kthr      memory          page          faults          cpu
-----
 r  b   avm   fre  re  pi  po  fr  sr  cy  in  sy  cs  us  sy  id  wa
0  1 75186  192  0  0  0  0  1  0 344 1998 403  6  2 92  0
```

To measure CPU and disk activity, use the **iostat** command:

```
# iostat 5 >iostat.output
```

This gives us a picture of the state of the system every 5 seconds during the measurement run. The first set of **iostat** output contains the cumulative data from the last boot to the start of the **iostat** command. The remaining sets are the results for the preceding interval, in this case 5 seconds. A typical set of **iostat** output on a system looks similar to the following:

```
tty:      tin          tout    avg-cpu:  % user    % sys    % idle    % iowait
          0.0          0.0          19.4     5.7     70.8     4.1

Disks:    % tm_act    Kbps     tps     Kb_read   Kb_wrtn
hdisk0    8.0        34.5     8.2     12        164
hdisk1    0.0        0.0     0.0     0         0
cd0       0.0        0.0     0.0     0         0
```

To measure memory, use the **svmon** command. The **svmon -G** command gives a picture of overall memory use. The statistics are in terms of 4 KB pages (example from AIX 4.3.3):

```
# svmon -G
```

```
memory    size      inuse     free      pin      virtual
pg space  65527    65406    121      5963     74711

          work     pers     cInt
pin       5972     0        0
in use   54177    9023     2206
```

In this example, the machine's 256 MB memory is fully used. About 83 percent of RAM is in use for working segments, the read/write memory of running programs (the rest is for caching files). If there are long-running processes in which we are interested, we can review their memory requirements in detail. The following example determines the memory used by a process of user hoetzal.

```
# ps -fu hoetzel
  UID  PID  PPID  C   STIME  TTY  TIME CMD
hoetzel 24896 33604  0 09:27:35 pts/3 0:00 /usr/bin/ksh
hoetzel 32496 25350  6 15:16:34 pts/5 0:00 ps -fu hoetzel

# svmon -P 24896
```

```
-----
  Pid Command      Inuse   Pin    Pgspace  Virtual  64-bit  Mthrd
24896 ksh           4592   1456   2711     5615     N       N

Vsid   Esid Type Description      Inuse   Pin Pgspace Virtual Addr Range
4411   d work shared library text 2619   0 1187 1315 0..65535
0      0 work kernel seg      1908 1455 1399 4171 0..32767 :
65475..65535

703c   1 pers code,/dev/hd2:4188 58     0 - - 0..58
5176   2 work process private    4     1 104 108 0..129 :
65309..65535

1465   - pers /dev/hd2:16866 2     0 - - 0..1
4858   - pers /dev/hd2:8254 1     0 - - 0..0
18c5   - pers /dev/andy:207 0     0 - - 0..0
783d   f work shared library data 0     0 21 21 0..3492
```

The working segment (5176), with 4 pages in use, is the cost of this instance of the **ksh** program. The 2619-page cost of the shared library and the 58-page cost of the **ksh** program are spread across all of the running programs and all instances of the **ksh** program, respectively.

If we believe that our 256 MB system is larger than necessary, use the **rmss** command to reduce the effective size of the machine and remeasure the workload. If paging increases significantly or response time deteriorates, we have reduced memory too much. This technique can be continued until we find a size that runs our workload without degradation. See *Assessing Memory Requirements Through the rmss Command* for more information on this technique.

The primary command for measuring network usage is the **netstat** program. The following example shows the activity of a specific Token-Ring interface:

```
# netstat -I tr0 5
  input      (tr0)      output
  packets  errs  packets  errs  colls  input  (Total)  output
  packets  errs  packets  errs  colls  packets  errs  packets  errs  colls
35552822 213488 30283693  0    0    35608011 213488 30338882  0    0
   300    0    426    0    0    300    0    426    0    0
   272    2    190    0    0    272    2    190    0    0
   231    0    192    0    0    231    0    192    0    0
   143    0    113    0    0    143    0    113    0    0
   408    1    176    0    0    408    1    176    0    0
```

The first line of the report shows the cumulative network traffic since the last boot. Each subsequent line shows the activity for the preceding 5-second interval.

Measuring a Complete Workload on a Production System

The techniques of measurement on production systems are similar to those on dedicated systems, but we must be careful to avoid degrading system performance.

Probably the most cost-effective tool is the **vmstat** command, which supplies data on memory, I/O, and CPU usage in a single report. If the **vmstat** intervals are kept reasonably long, for example, 10 seconds, the average cost is relatively low. See *Identifying the Performance-Limiting Resource* for more information on using the **vmstat** command.

Measuring a Partial Workload on a Production System

By partial workload, we mean measuring a part of the production system's workload for possible transfer to or duplication on a different system. Because this is a production system, we must be as unobtrusive as

possible. At the same time, we must analyze the workload in more detail to distinguish between the parts we are interested in and those we are not. To do a partial measurement, we must discover what the workload elements of interest have in common. Are they:

- The same program or a small set of related programs?
- Work performed by one or more specific users of the system?
- Work that comes from one or more specific terminals?

Depending on the commonality, we could use one of the following:

```
# ps -ef | grep pgmname
# ps -fuusername, . . .
# ps -ftttyname, . . .
```

to identify the processes of interest and report the cumulative CPU time consumption of those processes. We can then use the **svmon** command (judiciously) to assess the memory use of the processes.

Measuring an Individual Program

Many tools are available for measuring the resource consumption of individual programs. Some of these programs are capable of more comprehensive workload measurements as well, but are too intrusive for use on production systems. Most of these tools are discussed in depth in the chapters that discuss tuning for minimum consumption of specific resources. Some of the more prominent are:

svmon

Measures the real memory used by a process. Discussed in Determining How Much Memory Is Being Used.

time Measures the elapsed execution time and CPU consumption of an individual program. Discussed in Using the time Command to Measure CPU Use.

tprof Measures the relative CPU consumption of programs, subroutine libraries, and the operating system's kernel. Discussed in Using the tprof Program to Analyze Programs for CPU Use.

vmstat -s

Measures the I/O load generated by a program. Discussed in Assessing Overall Disk I/O with the vmstat Command.

Estimating Resources Required by a New Program

It is impossible to make precise estimates of unwritten programs. The invention and redesign that take place during the coding phase defy prediction, but the following guidelines can help you to get a general sense of the requirements. As a starting point, a minimal program would need the following:

- About 50 milliseconds of CPU time, mostly system time.
- Real Memory
 - One page for program text
 - About 15 pages (of which 2 are pinned) for the working (data) segment
 - Access to **libc.a**. Normally this is shared with all other programs and is considered part of the base cost of the operating system.
- About 12 page-in Disk I/O operations, if the program has not been compiled, copied, or used recently. Otherwise, none required.

To the above, add the basic cost allowances for demands implied by the design (the units given are for example purposes only):

- CPU time
 - The CPU consumption of an ordinary program that does not contain high levels of iteration or costly subroutine calls is almost unmeasurably small.
 - If the proposed program contains a computationally expensive algorithm, develop a prototype and measure the algorithm.

- If the proposed program uses computationally expensive library subroutines, such as X or Motif constructs or the **printf()** subroutine, measure their CPU consumption with otherwise trivial programs.
- Real Memory
 - Allow approximately 350 lines of code per page of program text, which is about 12 bytes per line. Keep in mind that coding style and compiler options can make a difference of a factor or two in either direction. This allowance is for pages that are touched in your typical scenario. If your design places infrequently executed subroutines at the end of the executable program, those pages do not normally consume real memory.
 - References to shared libraries other than **libc.a** increase the memory requirement only to the extent that those libraries are not shared with other programs or instances of the program being estimated. To measure the size of these libraries, write a trivial, long-running program that refers to them and use the **svmon -P** command against the process.
 - Estimate the amount of storage that will be required by the data structures identified in the design. Round up to the nearest page.
 - In the short run, each disk I/O operation will use one page of memory. Assume that the page has to be available already. Do not assume that the program will wait for another program's page to be freed.
- Disk I/O
 - For sequential I/O, each 4096 bytes read or written causes one I/O operation, unless the file has been accessed recently enough that some of its pages are still in memory.
 - For random I/O, each access, however small, to a different 4096-byte page causes one I/O operation, unless the file has been accessed recently enough that some of its pages are still in memory.
 - Each sequential read or write of a 4 KB page in a large file takes about 100 units. Each random read or write of a 4 KB page takes about 300 units. Remember that real files are not necessarily stored sequentially on disk, even though they are written and read sequentially by the program. Consequently, the typical CPU cost of an actual disk access will be closer to the random-access cost than to the sequential-access cost.
- Communications I/O
 - If disk I/O is actually to Network File System (NFS) remote-mounted file systems, the disk I/O is performed on the server, but the client experiences higher CPU and memory demands.
 - RPCs of any kind contribute substantially to the CPU load. The proposed RPCs in the design should be minimized, batched, prototyped, and measured in advance.
 - Each sequential NFS read or write of an 4 KB page takes about 600 units on the client. Each random NFS read or write of a 4 KB page takes about 1000 units on the client.
 - Web browsing and Web serving implies considerable network I/O, with TCP connections opening and closing quite frequently.

Transforming Program-Level Estimates to Workload Estimates

The best method for estimating peak and typical resource requirements is to use a queuing model such as BEST/1. Static models can be used, but you run the risk of overestimating or underestimating the peak resource. In either case, you need to understand how multiple programs in a workload interact from the standpoint of resource requirements.

If you are building a static model, use a time interval that is the specified worst-acceptable response time for the most frequent or demanding program (usually they are the same). Determine which programs will typically be running during each interval, based on your projected number of users, their think time, their key entry rate, and the anticipated mix of operations.

Use the following guidelines:

- CPU time

- Add together the CPU requirements for the all of the programs that are running during the interval. Include the CPU requirements of the disk and communications I/O the programs will be doing.
- If this number is greater than 75 percent of the available CPU time during the interval, consider fewer users or more CPUs.
- Real Memory
 - The operating system memory requirement scales with the amount of physical memory. Start with 6 to 8 MB for the operating system itself. The lower figure is for a standalone system. The latter figure is for a system that is LAN-connected and uses TCP/IP and NFS.
 - Add together the working segment requirements of all of the instances of the programs that will be running during the interval, including the space estimated for the program’s data structures.
 - Add to that total the memory requirement of the text segment of each distinct program that will be running (one copy of the program text serves all instances of that program). Remember that any (and only) subroutines that are from unshared libraries will be part of the executable program, but the libraries themselves will not be in memory.
 - Add to the total the amount of space consumed by each of the shared libraries that will be used by any program in the workload. Again, one copy serves all.
 - To allow adequate space for some file caching and the free list, your total memory projection should not exceed 80 percent of the size of the machine to be used.
- Disk I/O
 - Add the number of I/Os implied by each instance of each program. Keep separate totals for I/Os to small files (or randomly to large files) versus purely sequential reading or writing of large files (more than 32 KB).
 - Subtract those I/Os that you believe will be satisfied from memory. Any record that was read or written in the previous interval is probably still available in the current interval. Beyond that, examine the size of the proposed machine versus the total RAM requirements of the machine’s workload. Any space remaining after the operating system’s requirement and the workload’s requirements probably contains the most recently read or written file pages. If your application’s design is such that there is a high probability that you will reuse recently accessed data, you can calculate an allowance for the caching effect. Remember that the reuse is at the page level, not at the record level. If the probability of reuse of a given record is low, but there are a lot of records per page, it is likely that some of the records needed in any given interval will fall in the same page as other, recently used, records.
 - Compare the net I/O requirements (disk I/Os per second per disk) to the approximate capabilities of current disk drives. If the random or sequential requirement is greater than 75 percent of the total corresponding capability of the disks that will hold application data, tuning (and possibly expansion) will be needed when the application is in production.
- Communications I/O
 - Calculate the bandwidth consumption of the workload. If the total bandwidth consumption of all of the nodes on the LAN is greater than 70 percent of nominal bandwidth (50 percent for Ethernet), you might want to use a network with higher bandwidth.
 - Perform a similar analysis of CPU, memory, and I/O requirements of the added load that will be placed on the server.

Note: Remember that these guidelines are intended for use *only* when no extensive measurement is possible. Any application-specific measurement that can be used in place of a guideline will considerably improve the accuracy of the estimate.

Designing and Implementing Efficient Programs

If you have determined which resource will limit the speed of your program, you can go directly to the section that discusses appropriate techniques for minimizing the use of that resource. Otherwise, assume that the program will be balanced and that all of the recommendations in this chapter apply. Once the program is implemented, proceed to Identifying the Performance-Limiting Resource.

CPU-Limited Programs

The maximum speed of a truly processor-limited program is determined by:

- The algorithm used
- The source code and data structures created by the programmer
- The sequence of machine-language instructions generated by the compiler
- The sizes and structures of the processor's caches
- The architecture and clock rate of the processor itself (see Appendix D. Determining CPU Speed)

If the program is CPU-limited because it consists almost entirely of numerical computation, the chosen algorithm will have a major effect on the performance of the program. A discussion of alternative algorithms is beyond the scope of this book. It is assumed that computational efficiency has been considered in choosing the algorithm.

Given an algorithm, the only items in the preceding list that the programmer can affect are the source code, the compiler options used, and possibly the data structures. The following sections deal with techniques that can be used to improve the efficiency of an individual program for which the user has the source code. If the source code is not available, attempt to use tuning or workload-management techniques.

Design and Coding for Effective Use of Caches

In Chapter 1. Performance Concepts, we indicated that processors have a multilevel hierarchy of memory:

1. Instruction pipeline and the CPU registers
2. Instruction and data cache(s) and the corresponding translation lookaside buffers
3. RAM
4. Disk

As instructions and data move up the hierarchy, they move into storage that is faster than the level below it, but also smaller and more expensive. To obtain the maximum possible performance from a given machine, therefore, the programmer must make the most effective use of the available storage at each level.

Effective use of storage means keeping it full of instructions and data that are likely to be used. An obstacle to achieving this objective is the fact that storage is allocated in fixed-length blocks such as cache lines and real memory pages that usually do not correspond to boundaries within programs or data structures. Programs and data structures that are designed without regard to the storage hierarchy often make inefficient use of the storage allocated to them, with adverse performance effects in small or heavily loaded systems.

Taking the storage hierarchy into account means understanding and adapting to the general principles of efficient programming in a cached or virtual-memory environment. Repackaging techniques can yield significant improvements without recoding, and any new code should be designed with efficient storage use in mind.

Two terms are essential to any discussion of the efficient use of hierarchical storage: *locality of reference* and *working set*.

- The locality of reference of a program is the degree to which its instruction-execution addresses and data references are clustered in a small area of storage during a given time interval.
- The working set of a program during that same interval is the set of storage blocks that are in use, or, more precisely, the code or data that occupy those blocks.

A program with good locality of reference has a minimal working set, because the blocks that are in use are tightly packed with executing code or data. A functionally equivalent program with poor locality of reference has a larger working set, because more blocks are needed to accommodate the wider range of addresses being accessed.

Because each block takes a significant amount of time to load into a given level of the hierarchy, the objective of efficient programming for a hierarchical-storage system is to design and package code in such a way that the working set remains as small as practical.

The following figure illustrates good and bad practice at a subroutine level. The first version of the program is packaged in the sequence in which it was probably written. The first subroutine **PriSub1** contains the entry point of the program. It always uses primary subroutines **PriSub2** and **PriSub3**. Some infrequently used functions of the program require secondary subroutines **SecSub1** and **SecSub2**. On rare occasions, the error subroutines **ErrSub1** and **ErrSub2** are needed.

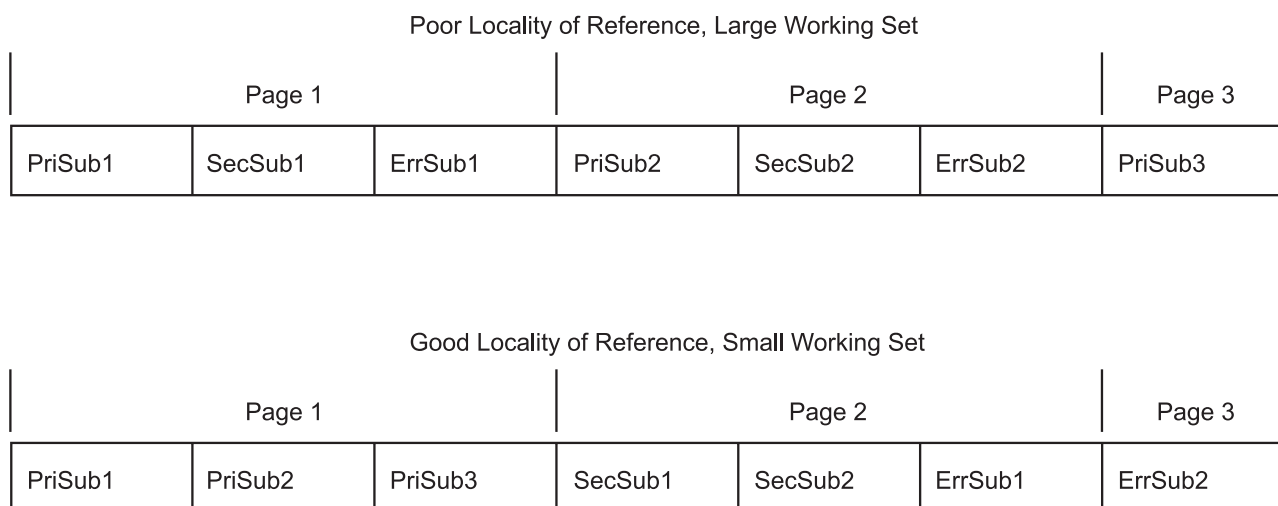

Figure 16. Locality of Reference. The top half of the figure describes how a binary program is packaged which shows low locality of reference. The instructions for PriSub1 is in the binary executable first, followed by the instructions for SecSub1, ErrSub1, PriSub2, SecSub2, ErrSub2, and PriSub3. In this executable, the instructions for PriSub1, SecSub1, and ErrSub1 occupy into the first page of memory. The instructions for PriSub2, SecSub2, and ErrSub2 occupy the second page of memory, and the instructions for PriSub3 occupy the third page of memory. SecSub1 and SecSub2 are infrequently used; also ErrSub1 and ErrSub2 are rarely used, if ever. Therefore, the packaging of this program exhibits poor locality of reference and may use more memory than required. In the second half of the figure, PriSub1, PriSub2, and PriSub3 are located next to each other and occupy the first page of memory. Following PriSub3 is SecSub1, SecSub2, and ErrSub1 which all occupy the second page of memory. Finally, ErrSub2 is at the end and occupies the third page of memory. Because ErrSub2 may never be needed, it would reduce the memory requirements by one page in this case.

The initial version of the program has poor locality of reference because it takes three pages of memory to run in the normal case. The secondary and error subroutines separate the main path of the program into three, physically distant sections.

The improved version of the program places the primary subroutines adjacent to one another and puts the low-frequency function after that. The necessary error subroutines (which are rarely-used) are left at the end of the executable program. The most common functions of the program can now be handled with only one disk read and one page of memory instead of the three previously required.

Remember that locality of reference and working set are defined with respect to time. If a program works in stages, each of which takes a significant time and uses a different set of subroutines, try to minimize the working set of each stage.

Registers and Pipeline

In general, allocating and optimizing of register space and keeping the pipeline full are the responsibilities of the compilers. The programmer's main obligation is to avoid structures that defeat compiler-optimization techniques. For example, if you use one of your subroutines in one of the critical loops of your program, it may be appropriate for the compiler to inline that subroutine to minimize execution time. If the subroutine has been packaged in a different .c module, however, it cannot be inlined by the compiler.

Cache and TLBs

Depending on the processor architecture and model, processors have from one to several caches to hold the following:

- Parts of executing programs
- Data used by executing programs
- Translation lookaside buffers (TLBs), which contain the mapping from virtual address to real address of recently used pages of instruction text or data

If a cache miss occurs, loading a complete cache line can take dozens of processor cycles. If a TLB miss occurs, calculating the virtual-to-real mapping of a page can take several dozen cycles. The exact cost is implementation-dependent.

Even if a program and its data fit in the caches, the more lines or TLB entries used (that is, the lower the locality of reference), the more CPU cycles it takes to get everything loaded in. Unless the instructions and data are reused many times, the overhead of loading them is a significant fraction of total program execution time, resulting in degraded system performance.

Good programming techniques keep the main-line, typical-case flow of the program as compact as possible. The main procedure and all of the subroutines it calls frequently should be contiguous. Low-probability conditions, such as obscure errors, should be tested for only in the main line. If the condition actually occurs, its processing should take place in a separate subroutine. All such subroutines should be grouped together at the end of the module. This arrangement reduces the probability that low-usage code will take up space in a high-usage cache line. In large modules, some or all of the low-usage subroutines might occupy a page that almost never has to be read into memory.

The same principle applies to data structures, although it is sometimes necessary to change the code to compensate for the compiler's rules about data layout.

For example, some matrix operations, such as matrix multiplication, involve algorithms that, if coded simplistically, have poor locality of reference. Matrix operations generally involve accessing the matrix data sequentially, such as row elements acting on column elements. Each compiler has specific rules about the storage layout of matrixes. The FORTRAN compiler lays out matrixes in column-major format (that is, all of the elements of column 1, followed by all the elements of column 2, and so forth). The C compiler lays out matrixes in row-major format. If the matrixes are small, the row and column elements can be contained in the data cache, and the processor and floating-point unit can run at full speed. However, as the size of the matrixes increases, the locality of reference of such row/column operations deteriorates to a point where the data can no longer be maintained in the cache. In fact, the natural access pattern of the row/column operations generates a thrashing pattern for the cache where a string of elements accessed is larger than the cache, forcing the initially accessed elements out and then repeating the access pattern again for the same data.

The general solution to such matrix access patterns is to partition the operation into blocks, so that multiple operations on the same elements can be performed while they remain in the cache. This general technique is given the name *strip mining*.

Experts in numerical analysis were asked to code versions of the matrix-manipulation algorithms that made use of strip mining and other optimization techniques. The result was a 30-fold improvement in

matrix-multiplication performance. The tuned routines are in the Basic Linear Algebra Subroutines (BLAS) library, `/usr/lib/libblas.a`. A larger set of performance-tuned subroutines is the Engineering and Scientific Subroutine Library (ESSL) licensed program.

The functions and interfaces of the Basic Linear Algebra Subroutines are documented in *AIX 5L Version 5.1 Technical Reference*. The FORTRAN run-time environment must be installed to use the library. Users should generally use this library for their matrix and vector operations because its subroutines are tuned to a degree that users are unlikely to achieve by themselves.

If the data structures are controlled by the programmer, other efficiencies are possible. The general principle is to pack frequently used data together whenever possible. If a structure contains frequently accessed control information and occasionally accessed detailed data, make sure that the control information is allocated in consecutive bytes. This will increase the probability that all of the control information will be loaded into the cache with a single (or at least with the minimum number of) cache misses.

Effective Use of Preprocessors and the Compilers

The programmer who wants to obtain the highest possible performance from a given program running on a given machine must deal with several considerations:

- There are preprocessors that can rearrange some source code structures to form a functionally equivalent source module that can be compiled into more efficient executable code.
- Just as there are several variants of the architecture, there are several compiler options to allow optimal compilation for a specific variant or set of variants.
- The programmer can use the **#pragma** feature to inform the C compiler of certain aspects of the program that will allow the compiler to generate more efficient code by relaxing some of its worst-case assumptions.
- There are several levels of optimization that give the compiler different degrees of freedom in instruction rearrangement.

Programmers who are unable to experiment, should always optimize. The difference in performance between optimized and unoptimized code is almost always so large that basic optimization (the **-O** option of the compiler commands) should always be used. The only exceptions are testing situations in which there is a specific need for straightforward code generation, such as statement-level performance analysis using the **tprof** tool.

These techniques yield additional performance improvement for some programs, but the determination of which combination yields the best performance for a specific program might require considerable recompilation and measurement.

For an extensive discussion of the techniques for efficient use of compilers, see *Optimization and Tuning Guide for XL Fortran, XL C and XL C++*.

Levels of Optimization

The levels of optimization in the compilers are as follows:

No Optimization

In the absence of any version of the **-O** flag, the compiler generates straightforward code with no instruction reordering or other attempt at performance improvement.

-O or **-O2**

These equivalent flags cause the compiler to optimize on the basis of conservative assumptions about code reordering. Only explicit relaxations such as the **#pragma** directives are used. This level performs no software pipelining, loop unrolling, or simple predictive commoning. It also constrains the amount of memory the compiler can use.

-O3

This flag directs the compiler to be aggressive about the optimization techniques used and to use as much memory as necessary for maximum optimization.

This level of optimization may result in functional changes to the program if the program is sensitive to the following:

- Floating-point exceptions
- The sign of zero
- Precision effects of reordering calculations

These side effects can be avoided, at some performance cost, by using the **-qstrict** option in combination with **-O3**.

The **-qhot** option, in combination with **-O3**, enables predictive commoning and some unrolling.

The result of these changes is that large or complex routines should have the same or better performance with the **-O3** option (possibly in conjunction with **-qstrict** or **-qhot**) that they had with the **-O** option in earlier versions of the compiler.

Compiling for Specific Hardware Platforms (-qarch, -qtune)

Systems can use several type of processors. By using the **-qarch** and **-qtune** options, you can optimize programs for the special instructions and particular strengths of these processors.

Follow these guidelines:

- If your program will be run only on a single system, or on a group of systems with the same processor type, use the **-qarch** option to specify the processor type.
- If your program will be run on systems with different processor types, and you can identify one processor type as the most important, use the appropriate **-qarch** and **-qtune** settings. FORTRAN and HPF users can use the **xxlf** and **xxlhpf** commands to select these settings interactively.
- If your program is intended to run on the full range of processor implementations, and is not intended primarily for one processor type, do not use either **-qarch** or **-qtune**.

C Options for string.h Subroutine Performance

The operating system provides the ability to embed the string subroutines in the application program rather than using them from **libc.a**, saving call and return linkage time. To embed the string subroutines, the source code of the application must have the following statement prior to the use of the subroutine(s):

```
#include <string.h>
```

C and C++ Coding Style for Best Performance

In many cases, the performance cost of a C construct is not obvious, and sometimes is even counter-intuitive. Some of these situations are as follows:

- Whenever possible, use *int* instead of *char* or *short*.

In most cases, *char* and *short* data items take more instructions to manipulate. The extra instructions cost time, and, except in large arrays, any space that is saved by using the smaller data types is more than offset by the increased size of the executable program.

- If you have to use a *char*, make it *unsigned*, if possible.

A *signed char* takes another two instructions more than an *unsigned char* each time the variable is loaded into a register.

- Use local (automatic) variables rather than global variables whenever possible.

Global variables require more instructions to access than local variables. Also, in the absence of information to the contrary, the compiler assumes that any global variable may have been changed by a

subroutine call. This change has an adverse effect on optimization because the value of any global variable used after a subroutine call will have to be reloaded.

- When it is necessary to access a global variable (that is not shared with other threads), copy the value into a local variable and use the copy.

Unless the global variable is accessed only once, it is more efficient to use the local copy.

- Use binary codes rather than strings to record and test for situations. Strings consume both data and instruction space. For example, the sequence:

```
#define situation_1 1
#define situation_2 2
#define situation_3 3
int situation_val;

situation_val = situation_2;
. . .
if (situation_val == situation_1)
. . .
```

is much more efficient than the following sequence:

```
char situation_val[20];

strcpy(situation_val,"situation_2");
. . .
if ((strcmp(situation_val,"situation_1"))==0)
. . .
```

- When strings are necessary, use fixed-length strings rather than null-terminated variable-length strings wherever possible.

The **mem*()** family of routines, such as **memcpy()**, is faster than the corresponding **str*()** routines, such as **strcpy()**, because the **str*()** routines must check each byte for null and the **mem*()** routines do not.

Compiler Execution Time

In the operating system, the C compiler can be invoked by two different commands: **cc** and **xlc**. The **cc** command, which has historically been used to invoke the system's C compiler, causes the C compiler to run in **langlevel=extended** mode. This mode allows the compilation of existing C programs that are not ANSI-compliant. It also consumes processor time.

If the program being compiled is, in fact, ANSI-compliant, it is more efficient to invoke the C compiler by using the **xlc** command.

Use of the **-O3** flag implicitly includes the **-qmaxmem** option. This option allows the compiler to use as much memory as necessary for maximum optimization. This situation can have two effects:

- On a multiuser system, a large **-O3** compilation may consume enough memory to have an adverse effect on the performance experienced by other users.
- On a system with small real memory, a large **-O3** compilation may consume enough memory to cause high paging rates, making compilation slow.

Memory-Limited Programs

To programmers accustomed to struggling with the addressing limitations of, for instance, the DOS environment, 256 MB virtual memory segments seem effectively infinite. The programmer is tempted to ignore storage constraints and code for minimum path length and maximum simplicity. Unfortunately, there is a drawback to this attitude. Virtual memory is large, but it is variable-speed. The more memory used, the slower it becomes, and the relationship is not linear. As long as the total amount of virtual storage actually being touched by all programs (that is, the sum of the working sets) is slightly less than the amount of unpinned real memory in the machine, virtual memory performs at about the speed of real memory. As the sum of the working sets of all executing programs passes the number of available page frames, memory performance degrades rapidly (if VMM memory load control is turned off) by up to two

orders of magnitude. When the system reaches this point, it is said to be *thrashing*. It is spending almost all of its time paging, and no useful work is being done because each process is trying to steal back from other processes the storage necessary to accommodate its working set. If VMM memory load control is active, it can avoid this self-perpetuating thrashing, but at the cost of significantly increased response times.

The degradation caused by inefficient use of memory is much greater than that from inefficient use of the caches because the difference in speed between memory and disk is so much higher than the difference between cache and memory. Where a cache miss can take a few dozen CPU cycles, a page fault typically takes 10 milliseconds or more, which is at least 400,000 CPU cycles.

Although VMM memory load control can ensure that incipient thrashing situations do not become self-perpetuating, unnecessary page faults still exact a cost in degraded response time and reduced throughput (see Tuning VMM Memory Load Control with the `schedtune` Command).

Structuring of Pageable Code

To minimize the code working set of a program, the general objective is to pack code that is frequently executed into a small area, separating it from infrequently executed code. Specifically:

- Do not put long blocks of error-handling code in line. Place them in separate subroutines, preferably in separate source-code modules. This applies not only to error paths, but to any functional option that is infrequently used.
- Do not structure load modules arbitrarily. Try to ensure that frequently called object modules are located as close to their callers as possible. Object modules consisting (ideally) of infrequently called subroutines should be concentrated at the end of the load module. The pages they inhabit will seldom be read in.

Structuring of Pageable Data

To minimize the data working set, try to concentrate the frequently used data and avoid unnecessary references to virtual-storage pages. Specifically:

- Use the **malloc()** or **calloc()** subroutines to request only as much space as you actually need. Never request and then initialize a maximum-sized array when the actual situation uses only a fraction of it. When you touch a new page to initialize the array elements, you effectively force the VMM to steal a page of real memory from someone. Later, this results in a page fault when the process that owned that page tries to access it again. The difference between the **malloc()** and **calloc()** subroutines is not just in the interface.
- Because the **calloc()** subroutine zeroes the allocated storage, it touches every page that is allocated, whereas the **malloc()** subroutine touches only the first page. If you use the **calloc()** subroutine to allocate a large area and then use only a small portion at the beginning, you place an unnecessary load on the system. Not only do the pages have to be initialized; if their real-memory frames are reclaimed, the initialized and never-to-be-used pages must be written out to paging space. This situation wastes both I/O and paging-space slots.
- Linked lists of large structures (such as buffers) can result in similar problems. If your program does a lot of chain-following looking for a particular key, consider maintaining the links and keys separately from the data or using a hash-table approach instead.
- Locality of reference means locality in time, not just in address space. Initialize data structures just prior to when they are used (if at all). In a heavily loaded system, data structures that are resident for a long time between initialization and use risk having their frames stolen. Your program would then experience an unnecessary page fault when it began to use the data structure.
- Similarly, if a large structure is used early and then left untouched for the remainder of the program, it should be released. It is not sufficient to use the **free()** subroutine to free the space that was allocated with the **malloc()** or **calloc()** subroutines. The **free()** subroutine releases only the address range that the structure occupied. To release the real memory and paging space, use the **disclaim()** subroutine to disclaim the space as well.

Misuse of Pinned Storage

To avoid circularities and time-outs, a small fraction of the system must be pinned in real memory. For this code and data, the concept of working set is meaningless, because all of the pinned information is in real storage all the time, whether or not it is used. Any program (such as a user-written device driver) that pins code or data must be carefully designed (or scrutinized, if ported) to ensure that only minimal amounts of pinned storage are used. Some cautionary examples are as follows:

- Code is pinned on a load-module (executable file) basis. If a component has some object modules that must be pinned and others that can be pageable, package the pinned object modules in a separate load module.
- Pinning a module or a data structure because there might be a problem is irresponsible. The designer should understand the conditions under which the information could be required and whether a page fault could be tolerated at that point.
- Pinned structures whose required size is load-dependent, such as buffer pools, should be tunable by the system administrator.

Using Performance-Related Installation Guidelines

This topic provides recommended actions you should take (or not take) before and during the installation process.

Operating System Preinstallation Guidelines

Two situations require consideration, as follows:

- Installing the Operating System on a New System

Before you begin the installation process, be sure that you have made decisions about the size and location of disk file systems and paging spaces, and that you understand how to communicate those decisions to the operating system.

- Installing a New Level of the Operating System on an Existing System

If you are upgrading to a new level of the operating system, do the following:

- Identify all uses in your present environment of the release-specific **schedtune** and **vmtune** performance tools. Because these tools can only be run by the root user, their use should not be widespread.
- If these programs are used during system boot, such as from **/etc/inittab**, they should be temporarily removed or bypassed until you are convinced by documentation or experiment that your use of these tools work correctly in the new release of the operating system.

CPU Preinstallation Guidelines

Use the default CPU scheduling parameters, such as the time-slice duration. Unless you have extensive monitoring and tuning experience with the same workload on a nearly identical configuration, leave these parameters unchanged at installation time.

See Chapter 6. Monitoring and Tuning CPU Use for post-installation recommendations.

Memory Preinstallation Guidelines

Do not make any memory-threshold changes until you have had experience with the response of the system to the actual workload.

See Chapter 7. Monitoring and Tuning Memory Use for post-installation recommendations.

Disk Preinstallation Guidelines

The mechanisms for defining and expanding logical volumes attempt to make the best possible default choices. However, satisfactory disk-I/O performance is much more likely if the installer of the system tailors the size and placement of the logical volumes to the expected data storage and workload requirements. Recommendations are as follows:

- If possible, the default volume group, rootvg, should consist only of the physical volume on which the system is initially installed. Define one or more other volume groups to control the other physical volumes in the system. This recommendation has system management, as well as performance, advantages.
- If a volume group consists of more than one physical volume, you may gain performance by:
 - Initially defining the volume group with a single physical volume.
 - Defining a logical volume within the new volume group. This definition causes the allocation of the volume group's journal logical volume on the first physical volume.
 - Adding the remaining physical volumes to the volume group.
 - Defining the high-activity file systems on the newly added physical volumes.
 - Defining only very-low-activity file systems, if any, on the physical volume containing the journal logical volume. This affects performance only if I/O would cause journaled file system (JFS) log transactions.

This approach separates journaled I/O activity from the high-activity data I/O, increasing the probability of overlap. This technique can have an especially significant effect on NFS server performance, because both data and journal writes must be complete before NFS signals I/O complete for a write operation.

- At the earliest opportunity, define or expand the logical volumes to their maximum expected sizes. To maximize the probability that performance-critical logical volumes will be contiguous and in the desired location, define or expand them first.
- High-usage logical volumes should occupy parts of multiple disk drives. If the **RANGE of physical volumes** option on the Add a Logical Volume screen of the SMIT program (fast path: **smitty mklv**) is set to **maximum**, the new logical volume will be divided among the physical volumes of the volume group (or the set of physical volumes explicitly listed).
- If the system has drives of different types (or you are trying to decide which drives to order), consider the following guidelines:
 - Place large files that are normally accessed sequentially on the fastest available disk drive.
 - If you expect frequent sequential accesses to large files on the fastest disk drives, limit the number of disk drivers per disk adapter.
 - When possible, attach drives with critical, high-volume performance requirements to a high speed adapter. These adapters have features, such as back-to-back write capability, that are not available on other disk adapters.
 - On the smaller disk drives, logical volumes that will hold large, frequently accessed sequential files should be allocated in the outer_edge of the physical volume. These disks have more blocks per track in their outer sections, which improves sequential performance.
 - On the original SCSI bus, the highest-numbered drives (those with the numerically largest SCSI addresses, as set on the physical drives) have the highest priority. Subsequent specifications usually attempt to maintain compatibility with the original specification. Thus, the order from highest to lowest priority is as follows: 7-6-5-4-3-2-1-0-15-14-13-12-11-10-9-8.

In most situations this effect is not noticeable, but large sequential file operations have been known to exclude low-numbered drives from access to the bus. You should probably configure the disk drives holding the most response-time-critical data at the highest addresses on each SCSI bus.

The **lsdev -Cs scsi** command reports on the current address assignments on each SCSI bus. For the original SCSI adapter, the SCSI address is the first number in the fourth pair of numbers in the output. In the following output example, one 400 GB disk is at SCSI address 4, another at address 5, the 8mm tape drive at address 1, and the CDROM drive is at address 3.

```

cd0    Available 10-80-00-3,0 SCSI Multimedia CD-ROM Drive
hdisk0 Available 10-80-00-4,0 16 Bit SCSI Disk Drive
hdisk1 Available 10-80-00-5,0 16 Bit SCSI Disk Drive
rmt0   Available 10-80-00-1,0 2.3 GB 8mm Tape Drive

```

- Large files that are heavily used and are normally accessed randomly, such as data bases, should be spread across two or more physical volumes.

See Chapter 8. Monitoring and Tuning Disk I/O Use for post-installation recommendations.

Placement and Sizes of Paging Spaces

The general recommendation is that the sum of the sizes of the paging spaces should be equal to at least twice the size of the real memory of the machine, up to a memory size of 256 MB (512 MB of paging space).

Note: For memories larger than 256 MB, the following is recommended:

$$\text{total paging space} = 512 \text{ MB} + (\text{memory size} - 256 \text{ MB}) * 1.25$$

However, starting with AIX 4.3.2 and Deferred Page Space Allocation, this guideline may tie up more disk space than actually necessary. See Choosing a Page Space Allocation Method.

Ideally, there should be several paging spaces of roughly equal size, each on a different physical disk drive. If you decide to create additional paging spaces, create them on physical volumes that are more lightly loaded than the physical volume in rootvg. When allocating paging space blocks, the VMM allocates four blocks, in turn, from each of the active paging spaces that has space available. While the system is booting, only the primary paging space (hd6) is active. Consequently, all paging-space blocks allocated during boot are on the primary paging space. This means that the primary paging space should be somewhat larger than the secondary paging spaces. The secondary paging spaces should all be of the same size to ensure that the algorithm performed in turn can work effectively.

The **lsps -a** command gives a snapshot of the current utilization level of all the paging spaces on a system. You can also use the **psdanger()** subroutine to determine how closely paging-space utilization is approaching critical levels. As an example, the following program uses the **psdanger()** subroutine to provide a warning message when a threshold is exceeded:

```

/* psmonitor.c
   Monitors system for paging space low conditions. When the condition is
   detected, writes a message to stderr.
   Usage:  psmonitor [Interval [Count]]
   Default: psmonitor 1 1000000
*/
#include <stdio.h>
#include <signal.h>
main(int argc, char **argv)
{
    int interval = 1;      /* seconds */
    int count = 1000000;  /* intervals */
    int current;          /* interval */
    int last;             /* check */
    int kill_offset;      /* returned by psdanger() */
    int danger_offset;    /* returned by psdanger() */

    /* are there any parameters at all? */
    if (argc > 1) {
        if ( (interval = atoi(argv[1])) < 1 ) {
            fprintf(stderr, "Usage: psmonitor [ interval [ count ] ]\n");
            exit(1);
        }
        if (argc > 2) {
            if ( (count = atoi( argv[2])) < 1 ) {
                fprintf(stderr, "Usage: psmonitor [ interval [ count ] ]\n");
                exit(1);
            }
        }
    }
}

```

```

    }
  }
}
last = count -1;
for(current = 0; current < count; current++) {
  kill_offset = psdanger(SIGKILL); /* check for out of paging space */
  if (kill_offset < 0)
    fprintf(stderr,
      "OUT OF PAGING SPACE! %d blocks beyond SIGKILL threshold.\n",
      kill_offset*(-1));
  else {
    danger_offset = psdanger(SIGDANGER); /* check for paging space low */
    if (danger_offset < 0) {
      fprintf(stderr,
        "WARNING: paging space low. %d blocks beyond SIGDANGER threshold.\n",
        danger_offset*(-1));
      fprintf(stderr,
        "
          %d blocks below SIGKILL threshold.\n",

}

```

Performance Implications of Disk Mirroring

If mirroring is being used and Mirror Write Consistency is on (as it is by default), consider locating the copies in the outer region of the disk, because the Mirror Write Consistency information is always written in Cylinder 0. From a performance standpoint, mirroring is costly, mirroring with Write Verify is costlier still (extra disk rotation per write), and mirroring with both Write Verify and Mirror Write Consistency is costliest of all (disk rotation plus a seek to Cylinder 0). From a fiscal standpoint, only mirroring with writes is expensive. Although an **islv** command will usually show Mirror Write Consistency to be on for non-mirrored logical volumes, no actual processing is incurred unless the COPIES value is greater than one. Write Verify defaults to off, because it does have meaning (and cost) for non-mirrored logical volumes.

Performance Implications of Mirrored Striped LVs

Prior to AIX 4.3.3, logical volumes could not be mirrored and striped at the same time. Logical volume mirroring and striping combines the data availability of RAID 1 with the performance of RAID 0 entirely through software. Volume groups that contain striped and mirrored logical volumes cannot be imported into AIX 4.3.2 or earlier.

Communications Preinstallation Guidelines

See the summary of communications tuning recommendations in Tuning TCP and UDP Performance and Tuning mbuf Pool Performance.

For correct placement of adapters and various performance guidelines, see *PCI Adapter Placement Reference*.

Chapter 5. System Monitoring and Initial Performance Diagnosis

This chapter describes tools and techniques for monitoring performance-related system activity and diagnosing performance problems. The major sections are:

- The Case for Continuous Performance Monitoring
- Using the `vmstat`, `iostat`, `netstat`, and `sar` Commands
- Using the `topas` Monitor
- Using the Performance Diagnostic Tool
- Using the Performance Toolbox
- Determining the Kind of Performance Problem Reported
- Identifying the Performance-Limiting Resource
- Managing Workload

The Case for Continuous Performance Monitoring

In some installations, performance activity is monitored on a demand basis. When a performance problem is reported, the performance analyst runs one or more commands in an attempt to determine why the problem occurred. In some cases, explicit recreation of the problem is needed in order to collect analysis data. The result is that users experience every performance problem twice.

It is usually more effective to monitor performance continuously, preferably with automatic collection of additional data if performance deteriorates. The costs of continuous monitoring are outweighed by the advantages, such as:

- Monitoring can sometimes detect incipient problems before they have an adverse effect.
- Monitoring can detect problems that happen to users who are reluctant to complain, as well as problems that are not quite severe enough to complain about, but are affecting productivity and morale.
- Monitoring can collect data when a problem occurs for the first time.

Successful monitoring involves the following main activities:

- Periodically obtaining performance-related information from the operating system
- Storing the information for future use in problem diagnosis
- Displaying the information for the benefit of the system administrator
- Detecting situations that require additional data collection or responding to directions from the system administrator to collect such data, or both
- Collecting and storing the necessary detail data

The following sections discuss several approaches to continuous monitoring. These approaches are not mutually exclusive, but use of more than one may involve some redundancy.

Using the `vmstat`, `iostat`, `netstat`, and `sar` Commands

The `vmstat`, `iostat`, `netstat`, and `sar` commands have functional characteristics that make them useful for continuous monitoring of system performance. These commands can:

- Produce reports indefinitely at a fixed interval
- Report on activity that varies with different types of load
- Report on activity since the last previous report (except the `sar` command), so changes in activity are easy to detect

The following example shows samples of the periodic reports produced by these programs.

```
# vmstat 5 2
kthr      memory          page          faults          cpu
-----
 r  b   avm    fre  re  pi  po  fr  sr  cy  in  sy  cs  us  sy  id  wa
0  1 75318  142  0  0  0  0  0  0 299 1845 315  5  2 93  0
0  1 75318  141  0  0  0  0  0  0 626 4949 842  8  6 87  0
```

See The `vmstat` Command (CPU), The `vmstat` Command (Memory), and Assessing Disk Performance with the `vmstat` Command for detailed discussions of the `vmstat` command.

```
# iostat 5 2

tty:      tin          tout  avg-cpu:  % user   % sys    % idle   % iowait
0.0              0.5      5.2     1.8     92.7     0.3
" Disk history since boot not available. "

tty:      tin          tout  avg-cpu:  % user   % sys    % idle   % iowait
0.0              41.4     8.1     5.5     84.2     2.2

Disks:    % tm_act    Kbps     tps     Kb_read  Kb_wrtn
hdisk0    7.1         28.4     6.9     0        144
hdisk1    0.0         0.0     0.0     0         0
cd0       0.0         0.0     0.0     0         0
```

The system maintains a history of disk activity. If the history is disabled (`smitty chgsys -> Continuously maintain DISK I/O history [false]`) you see this message when running the `iostat` command: Disk history since boot not available. The interval disk I/O statistics are unaffected by this. For detailed discussion of this command, see The `iostat` Command and Assessing Disk Performance with the `iostat` Command.

```
# netstat -I tr0 5
input      (tr0)      output      input      (Total)      output
packets  errs  packets  errs  colls  packets  errs  packets  errs  colls
725227  0    445748  0    0    799996  0    520517  0    0
0        0    0        0    0    0        0    0        0    0
2        0    0        0    0    2        0    0        0    0

CTRL C
```

Other useful `netstat` command options to use are `-s` and `-v`. See The `netstat` Command for details.

```
# sar -P ALL 5 2

AIX rugby 3 4 00058033A100    12/01/99

          -      0      0      0      100
```

For details on the `sar` command, see The `sar` Command and Assessing Disk Performance with the `sar` Command.

Remember that the first report from the **vmstat**, **iostat**, and **netstat** commands is for cumulative activity since the last system boot. The second report shows activity for the first 5-second interval. The **sar** command does not report the cumulative activity since the last system boot.

These commands are the basic foundation on which to construct a performance-monitoring mechanism. Shell scripts can be written to perform data reduction on the command output and warn of performance problems or record data on the status of the system when a problem is occurring. For example, a shell script could test the CPU idle percentage for zero and execute another shell script when that CPU-saturated condition occurred. A script such as:

```
# ps -ef | egrep -v "STIME|$LOGNAME" | sort +3 -r | head -n 15
```

would record the 15 active processes that had consumed the most CPU time recently (other than the processes owned by the user of the script).

Depending on the required level of sophistication, creating such a family of shell scripts can be a substantial project. Fortunately, there are packages available that require less development and setup and have considerably more function than the typical installation would want to implement locally.

Using the topas Monitor

The **topas** command reports vital statistics about the activity on the local system in a character terminal. It requires the operating system version 4.3.3 or later with the **perfagent.tools** fileset installed on the system.

The program extracts and displays statistics from the system with a default interval of two seconds. On the operating system version 4.3.3, the output consists on two fixed part and one variable section.

The top two lines at the left of the output show the name of the system the **topas** program runs on, the date and time of the last observation, and the monitoring interval. Following that is a fixed section which lists the CPU utilization in both numeric and block-graph format.

The second fixed section fills the rightmost 32 positions of the output. It contains five subsections of statistics, EVENTS/QUEUES, FILE/TTY, PAGING, MEMORY and PAGING SPACE.

The variable part of **topas** running on the operating system version 4.3.3, can have one, two or three subsections. If more than one appears, the subsections are always shown in the following order:

- Network Interfaces
- Physical Disks
- Processes

The three sections present respectively, a sorted list of the busiest network interfaces, disks, and processes. The following is an example of the output generated by the **topas** command running on the operating system 4.3.3:

```
Topas Monitor for host:   lambic           EVENTS/QUEUES   FILE/TTY

```

Press "h" for help screen.
Press "q" to quit program.

On the operating system Version 5, the **topas** program has been enhanced to add two alternate screens, the CPU utilization report has become an optional subsection, and the fixed section includes an additional subsection with NFS statistics, while the variable section includes a new WLM subsection. The complete list of optional subsections on the operating system version 5, in the order in which they are displayed is:

- CPU utilization
- Network Interfaces
- Physical Disks
- WLM classes
- Processes

Here is an example of the main screen when the **topas** program runs on the operating system version 5:

```

Topas Monitor for host:  mothra      EVENTS/QUEUES  FILE/TTY
Wed Nov  8 12:32:12 2000  Interval:  2    Cswitch       25  Readch        0
                               Syscall       24  Writech       23
                               Reads            0  Rawin         0
                               Writes            0  Ttyout        0
                               Forks            0  Igets         0
                               Execs            0  Namei         0
                               Runqueue        0.0  Dirblk        0

```

Additionally, except for the Process variable subsection, all subsections can be sorted by any of their columns by simply moving the cursor on top of the desired column. All variable subsections, except the Processes list, now have two views, one presenting the top resource users, and another view presenting the sum of the activity in a one line report: showing the total disk or network throughput for instance. For the CPU subsection, the user can select either the list of busiest processors, or the global CPU utilization as shown in the previous example.

On the operating system version 5, two additional screens are available. The first alternate screen (reachable with the **P** command or the **-P** flag), presents the list of busiest processes, similar to the processes subsection of the main screen, but with more columns. This screen is sortable by any of its columns. Here is an example of such a display:

```

Topas Monitor for host:  mothra      Interval:  2   Wed Nov  8 12:27:34 2000
                        DATA TEXT PAGE          PGFAULTS

```

The second alternate screen (reachable with the **W** command, or the **-W** flag), is divided in two sections. The top section is the same list of busiest WLM classes as presented in the WLM subsection of the main screen, also sortable by any of its columns. When the user selects one the WLM classes shown using the arrow keys and the "f" key, the second section of the screen will show the list of hot processes within the selected WLM class. Here is an example of the WLM full screen report:

```

Topas Monitor for host:  mothra      Interval:  2   Wed Nov  8 12:30:54 2000
WLM-Class (Active)      CPU%      Mem%      Disk-I/O%
System                  0          0          0
Shared                  0          0          0
Default                 0          0          0
Unmanaged               0          0          0
Unclassified            0          0          0

```

```

```

The individual command line flags, commands, and sections are described in the formal documentation of the **topas** command in the *AIX 5L Version 5.1 Commands Reference*.

Using the Performance Diagnostic Tool

The Performance Diagnostic Tool (PDT) is a tool available in operating system version 4. PDT collects configuration and performance information and attempts to identify potential problems, both current and future.

PDT is an optionally installable component of the Base Operating System. Its name is **bos.perf.diag_tool**. After PDT has been installed, it must be activated with the **/usr/sbin/perf/diag_tool/pdt_config** command. This causes appropriate entries to be made in the **crontab** file, which causes PDT to run periodically, recording data and looking for new trends.

In assessing the configuration and the historical record of performance measurements, PDT attempts to identify:

- Resource imbalances: asymmetrical aspects of configuration or device utilization
- Usage trends: changes in usage levels that will lead to saturation
- New consumers of resources: expensive processes that have not been observed previously
- Inappropriate system parameter values: settings that may cause problems
- Errors: hardware or software problems that may lead to performance problems

PDT is described in detail in Chapter 13. Using Performance Diagnostic Tool (PDT).

Using the Performance Toolbox

The Performance Toolbox (PTX) is a licensed product that allows graphical display of a variety of performance-related metrics. Among the advantages of PTX over ASCII reporting programs is that it is much easier to check current performance with a glance at the graphics monitor than by looking at a screen full of numbers. PTX also facilitates the combination of information from multiple performance-related commands and allows recording and playback.

PTX contains tools for local and remote system-activity monitoring and tuning. The product consists of two main components: the PTX Manager and the PTX Agent. The PTX Agent is available as a separate licensed product called the Performance Aide for AIX. The following figure shows a simplified LAN configuration in which the PTX Manager is monitoring the activity of several systems.

Figure 17. LAN Configuration Using Performance Toolbox. This illustration shows five nodes of a local area network that are connected using the star topology. Each node on the network has the performance toolbox (PTX) agent running on it. One of the nodes is the PTX Manager and can monitor the other nodes via the resident agent.

The main purpose of the PTX Manager is to collect and display data from the various systems in the configuration. The primary program for this purpose is `xmperf`. The primary program used by the Agent to collect and transmit data to the Manager is `xmservd`.

PTX is described in detail in the *Performance Toolbox Version 2 and 3 for AIX: Guide and Reference* and *Customizing Performance Toolbox and Performance Toolbox Extensions for AIX*.

Recording with the Performance Agent

If you need to record information or a playback facility, several tools are included with the manager code (`xmperf`, `3dmon`, `azizo`, `ptxrlog`). Other tools (`xmservd`, `ptxtab`, `ptxsplit`) are packaged with the agent code.

Best suited for continuous monitoring are the following tools:

- The `ptxrlog` command can produce recordings in ASCII format, which allows you to print the output or post-process it, or it can produce a recording file in binary to be viewed with the `azizo` or `xmperf` commands.
- The `xmservd` daemon can act as a recording facility and is controlled through the `xmservd.cf` configuration file.

Determining the Kind of Performance Problem Reported

When a performance problem is reported, determining the kind of performance problem often helps the performance analyst to narrow the list of possible culprits.

A Particular Program Runs Slowly

Although this situation might seem trivial, there are still questions to be asked:

- Has the program always run slowly?
If the program has just started running slowly, a recent change might be the cause.
- Has the source code been changed or a new version installed?
If so, check with the programmer or vendor.
- Has something in the environment changed?

If a file used by the program (including its own executable program) has been moved, it may now be experiencing Local Area Network (LAN) delays that did not exist previously. Or, files may be contending for a single disk accessor that were on different disks previously.

If the system administrator has changed system-tuning parameters, the program may be subject to constraints that it did not experience previously. For example, if the **schedtune -r** command has been used to change the way priority is calculated, programs that used to run rather quickly in the background may now be slowed down, while foreground programs have speeded up.

- Is the program written in the **perl**, **awk**, **csh**, or some other interpretive language?

While they allow programs to be written quickly, interpretive languages have the problem that they are not optimized by a compiler. Also, it is easy in a language like **perl** or **awk** to request an extremely compute- or I/O-intensive operation with a few characters. It is often worthwhile to perform a desk check or informal peer review of such programs with the emphasis on the number of iterations implied by each operation.

- Does the program always run at the same speed, or is it sometimes faster?

The file system uses some of system memory to hold pages of files for future reference. If a disk-limited program is run twice in quick succession, it will normally run faster the second time than the first.

Similar phenomena might be observed with programs that use NFS. This can also occur with large programs, such as compilers. The program's algorithm might not be disk-limited, but the time needed to load a large executable program might make the first execution of the program much longer than subsequent ones.

- If the program has always run slowly, or has slowed down without any obvious change in its environment, look at its dependency on resources.

Identifying the Performance-Limiting Resource describes techniques for finding the bottleneck.

Everything Runs Slowly at a Particular Time of Day

Most people have experienced the rush-hour slowdown that occurs because a large number of people in the organization habitually use the system at one or more particular times each day. This phenomenon is not always simply due to a concentration of load. Sometimes it is an indication of an imbalance that is (at present) only a problem when the load is high. Other sources of recurring situations in the system should be considered.

- If you run the **iostat** and **netstat** commands for a period that spans the time of the slowdown (or have previously captured data from your monitoring mechanism), are some disks much more heavily used than others? Is the CPU idle percentage consistently near zero? Is the number of packets sent or received unusually high?
 - If the disks are unbalanced, see Chapter 8. Monitoring and Tuning Disk I/O Use.
 - If the CPU is saturated, use the **ps** or **topas** commands to identify the programs being run during this period. The script given in Using the vmstat, iostat, netstat, and sar Commands simplifies the search for the heaviest CPU users.
 - If the slowdown is counter-intuitive, such as paralysis during lunch time, look for a pathological program such as a graphic **xlock** or game program. Some versions of the **xlock** program are known to use huge amounts of CPU time to display graphic patterns on an idle display. It is also possible that someone is running a program that is a known CPU burner and is trying to run it at the least intrusive time.
- Unless your **/var/adm/cron/cron.allow** file is null, you may want to check the contents of the **/var/adm/cron/crontab** directory for expensive operations.

If you find that the problem stems from conflict between foreground activity and long-running, CPU-intensive programs that are, or should be, run in the background, consider using the command **schedtune -r -d** to give the foreground higher priority. See Tuning the Thread-Priority-Value Calculation.

Everything Runs Slowly at Unpredictable Times

The best tool for this situation is an overload detector, such as the **filtd** program (a component of PTX). The **filtd** daemon can be set up to execute shell scripts or collect specific information when a particular condition is detected. You can construct a similar, but more specialized, mechanism using shell scripts containing the **vmstat**, **iostat**, **netstat**, **sar**, and **ps** commands.

If the problem is local to a single system in a distributed environment, there is probably a pathological program at work, or perhaps two that intersect randomly.

Everything That an Individual User Runs is Slow

Sometimes a system seems to "single out" an individual.

- Quantify the problem. Ask the user which commands he uses frequently, and run them with the **time** command, as in the following example:

```
# time cp .profile testjunk
real    0m0.08s
user    0m0.00s
sys     0m0.01s
```

Then run them under a satisfactory user ID. Is there a difference in the reported real time?

- A program should not show much CPU time (user+sys) difference from run to run, but may show a real time difference because of more or slower I/O. Are the user's files on an NFS-mounted directory? On a disk that has high activity for other reasons?
- Check the user's **.profile** file for unusual \$PATH specifications. For example, if you always search a couple of NFS-mounted directories (fruitlessly) before searching **/usr/bin**, everything will take longer.

A Number of LAN-Connected Systems Slow Down Simultaneously

There are some common problems that arise in the transition from independent systems to distributed systems. The problems usually result from the need to get a new configuration running as soon as possible, or from a lack of awareness of the cost of certain functions. In addition to tuning the LAN configuration in terms of maximum transmission units (MTU) and mbufs (see Chapter 9. Monitoring and Tuning Communications I/O Use), look for LAN-specific pathologies or nonoptimal situations that may have evolved through a sequence of individually reasonable decisions.

- Use network statistics to ensure that there are no physical network problems. Ensure that commands such as **netstat -v**, **entstat**, **tokstat**, **atmstat**, or **fd distat** do not show excessive errors or collision on the adapter.
- Some types of software or firmware bugs can sporadically saturate the LAN with broadcast or other packets.

When a broadcast storm occurs, even systems that are not actively using the network can be slowed by the incessant interrupts and by the CPU resource consumed in receiving and processing the packets. These problems are better detected and localized with LAN analysis devices than with the normal performance tools.

- Do you have two LANs connected through a system?

Using a system as a router consumes large amounts of CPU time to process and copy packets. It is also subject to interference from other work being processed by the system. Dedicated hardware routers and bridges are usually a more cost-effective and robust solution to the need to connect LANs.

- Is there a clearly defensible purpose for each NFS mount?

At some stages in the development of distributed configurations, NFS mounts are used to give users on new systems access to their home directories on their original systems. This situation simplifies the initial transition, but imposes a continuing data communication cost. It is not unknown to have users on system A interacting primarily with data on system B and vice versa.

Access to files through NFS imposes a considerable cost in LAN traffic, client and server CPU time, and end-user response time. A general guideline is that user and data should normally be on the same

system. The exceptions are those situations in which an overriding concern justifies the extra expense and time of remote data. Some examples are a need to centralize data for more reliable backup and control, or a need to ensure that all users are working with the most current version of a program.

If these and other needs dictate a significant level of NFS client-server interchange, it is better to dedicate a system to the role of server than to have a number of systems that are part-server, part-client.

- Have programs been ported correctly (and justifiably) to use remote procedure calls (RPCs)?

The simplest method of porting a program into a distributed environment is to replace program calls with RPCs on a 1:1 basis. Unfortunately, the disparity in performance between local program calls and RPCs is even greater than the disparity between local disk I/O and NFS I/O. Assuming that the RPCs are really necessary, they should be batched whenever possible.

Everything on a Particular Service or Device Slows Down at Times

If everything that uses a particular device or service slows down at times, refer to the topic that covers that particular device or service:

- Chapter 6. Monitoring and Tuning CPU Use
- Chapter 7. Monitoring and Tuning Memory Use
- Chapter 8. Monitoring and Tuning Disk I/O Use
- Chapter 9. Monitoring and Tuning Communications I/O Use

Make sure you have followed the configuration recommendations in the appropriate subsystem manual and the recommendations in the appropriate "Monitoring and Tuning" chapter of this book.

Identifying the Performance-Limiting Resource

Perhaps the best tool for an overall look at resource utilization while running a multiuser workload is the **vmstat** command. The **vmstat** command reports CPU and disk-I/O activity, as well as memory utilization data. The following command causes the **vmstat** command to begin writing a one-line summary report of system activity every 5 seconds:

```
# vmstat 5
```

Because no count was specified following the interval, reporting continues until the command is canceled.

The following **vmstat** report was made on a system running AIXwindows and several synthetic applications (some low-activity intervals have been removed for example purposes):

kthr		memory				page				faults				cpu			
r	b	avm	fre	re	pi	po	fr	sr	cy	in	sy	cs	us	sy	id	wa	
0	0	8793	81	0	0	0	1	7	0	125	42	30	1	2	95	2	
0	0	8793	80	0	0	0	0	0	0	155	113	79	14	8	78	0	
0	0	8793	57	0	3	0	0	0	0	178	28	69	1	12	81	6	
0	0	9192	66	0	0	16	81	167	0	151	32	34	1	6	77	16	
0	0	9193	65	0	0	0	0	0	0	117	29	26	1	3	96	0	
0	0	9193	65	0	0	0	0	0	0	120	30	31	1	3	95	0	
0	0	9693	69	0	0	53	100	216	0	168	27	57	1	4	63	33	
0	0	9693	69	0	0	0	0	0	0	134	96	60	12	4	84	0	
0	0	10193	57	0	0	0	0	0	0	124	29	32	1	3	94	2	
0	0	11194	64	0	0	38	201	1080	0	168	29	57	2	8	62	29	
0	0	11194	63	0	0	0	0	0	0	141	111	65	12	7	81	0	
0	0	5480	755	3	1	0	0	0	0	154	107	71	13	8	78	2	
0	0	5467	5747	0	3	0	0	0	0	167	39	68	1	16	79	5	
0	1	4797	5821	0	21	0	0	0	0	191	192	125	20	5	42	33	
0	1	3778	6119	0	24	0	0	0	0	188	170	98	5	8	41	46	
0	0	3751	6139	0	0	0	0	0	0	145	24	54	1	10	89	0	

The columns of interest for this initial assessment are `pi` and `po` in the page category and the four columns in the `cpu` category.

- Entries `pi` and `po` are the paging-space page ins and page outs, respectively. If any paging-space I/O is taking place, the workload may be approaching (or is beyond) the system's memory limits.
- If the sum of `us` and `sy` (user and system) CPU-utilization percentages is greater than 90 percent in a given 5-second interval, the workload was approaching the CPU limits of the system during that interval.
- If the `wa` (I/O wait) percentage is close to zero (and `pi` and `po` are zero), some time is being spent waiting on nonoverlapped file I/O, and some part of the workload is I/O-limited.

By "approaching" its limits, we mean that some parts of the workload are already experiencing a slowdown due to the critical resource. The longer response times might not be subjectively significant yet, but an increase in that element of the workload will cause a rapid deterioration of performance.

If the **`vmstat`** command indicates a significant amount of I/O wait time, the **`iostat`** command will give more detailed information. The following command causes the **`iostat`** command to begin writing summary reports of I/O activity and CPU utilization every 5 seconds:

```
# iostat 5 3
```

Because a count of 3 was specified following the interval, reporting will stop after the third report.

The following **`iostat`** report was made on a system running the same workload as the **`vmstat`** reports above, but at a different time. The first report is for the cumulative activity since the preceding boot, while subsequent reports are for activity during the preceding 5-second interval:

```
tty:      tin          tout    avg-cpu:  % user   % sys    % idle   %iowait
          0.0          4.3      0.2      0.2     0.6     98.8     0.4
```

```
Disks:    % tm_act    Kbps     tps     Kb_read  Kb_wrtn

hdisk2    98.4        575.6    61.9      396     2488
cd0       0.0         0.0      0.0        0         0
```

The first report, which displays cumulative activity since the last boot, shows that the I/O on this system is unbalanced. Most of the I/O (86.9 percent of kilobytes read and 90.7 percent of kilobytes written) is to `hdisk2`, which contains both the operating system and the paging space. The cumulative CPU utilization since boot statistic is usually meaningless, unless the system is used consistently 24 hours a day.

The second report shows a small amount of disk activity reading from `hdisk0`, which contains a separate file system for the system's primary user. The CPU activity arises from two application programs and the **`iostat`** command itself. Although the output of the **`iostat`** command is redirected to a file, the output is not voluminous, and the system is not sufficiently memory-constrained to force any output during this interval.

In the third report, we have artificially created a near-thrashing condition by running a program that allocates, and stores into, a large amount of memory (about 26 MB in this example). In the example, `hdisk2` is active 98.4 percent of the time, which results in 93.8 percent I/O wait.

If the `vmstat` command indicates that there is a significant amount of CPU idle time when the system seems subjectively to be running slowly, you might be experiencing delays due to kernel lock contention. This possibility can be investigated with the `lockstat` command (only available in AIX Version 4).

Determining the Limiting Factor for a Single Program

If you are the sole user of a system, you can get a general idea of whether a program is I/O or CPU dependent by using the `time` command as follows:

```
# time cp foo.in foo.out
```

```
real    0m0.13s
user    0m0.01s
sys     0m0.02s
```

Note: Examples of the `time` command here and elsewhere in this guide use the version that is built into the Korn shell (`ksh`). The official `time` command (`/usr/bin/time`) reports with a lower precision.

In this example, the fact that the real, elapsed time for the execution of the `cp` program (.13 seconds) is significantly greater than the sum (.03 seconds) of the user and system CPU times indicates that the program is I/O bound. This occurs primarily because the `foo.in` file has not been read recently.

On an SMP the output takes on a new meaning. See `time` and `timex` Cautions.

Running the same command a few seconds later against the same file gives the following output:

```
real    0m0.06s
user    0m0.01s
sys     0m0.03s
```

Most or all of the pages of the `foo.in` file are still in memory because there has been no intervening process to cause them to be reclaimed and because the file is small compared with the amount of RAM on the system. A small `foo.out` file would also be buffered in memory, and a program using it as input would show little disk dependency.

If you are trying to determine the disk dependency of a program, you must be sure that its input is in an authentic state. That is, if the program will normally be run against a file that has not been accessed recently, you must make sure that the file used in measuring the program is not in memory. If, on the other hand, a program is usually run as part of a standard sequence in which it gets its input from the output of the preceding program, you should prime memory to ensure that the measurement is authentic. For example, the following command would have the effect of priming memory with the pages of the `foo.in` file:

```
# cp foo.in /dev/null
```

The situation is more complex if the file is large compared to RAM. If the output of one program is the input of the next and the entire file will not fit in RAM, the second program will read pages at the head of the file, which displaces pages at the end. Although this situation is very hard to simulate authentically, it is nearly equivalent to one in which no disk caching takes place.

The case of a file that is (perhaps just slightly) larger than RAM is a special case of the RAM versus disk analysis discussed in the next section.

Determining Whether the Problem is Related to Disk or Memory

Just as a large fraction of real memory is available for buffering files, the system's page space is available as temporary storage for program working data that has been forced out of RAM. Suppose that you have a program that reads little or no data and yet shows the symptoms of being I/O dependent. Worse, the ratio of real time to user + system time does not improve with successive runs. The program is probably memory-limited, and its I/O is to, and possibly from the paging space. A way to check on this possibility is shown in the following **vmstatit** (or in AIX 5.1, see the **vmstat -l** option) shell script:

```
vmstat -s >temp.file # cumulative counts before the command
time $1 # command under test
vmstat -s >>temp.file # cumulative counts after execution
grep "pagi.*ins" temp.file >>results # extract only the data
grep "pagi.*outs" temp.file >>results # of interest
```

The **vmstatit** script summarizes the voluminous **vmstat -s** report, which gives cumulative counts for a number of system activities since the system was started.

If the shell script is run as follows:

```
# vmstatit "cp file1 file2" 2>results
```

the result is as follows:

```
real    0m0.03s
user    0m0.01s
sys     0m0.02s
      2323 paging space page ins
      2323 paging space page ins
      4850 paging space page outs
      4850 paging space page outs
```

The before-and-after paging statistics are identical, which confirms our belief that the **cp** command is not paging-bound. An extended variant of the **vmstatit** shell script can be used to show the true situation, as follows:

```
vmstat -s >temp.file
time $1
vmstat -s >>temp.file
echo "Ordinary Input:" >>results
grep "[ 0-9]*page ins" temp.file >>results
echo "Ordinary Output:" >>results
grep "[ 0-9]*page outs" temp.file >>results
echo "True Paging Output:" >>results
grep "pagi.*outs" temp.file >>results
echo "True Paging Input:" >>results
grep "pagi.*ins" temp.file >>results
```

Because file I/O in the operating system is processed through the VMM, the **vmstat -s** command reports ordinary program I/O as page ins and page outs. When the previous version of the **vmstatit** shell script was run against the **cp** command of a large file that had not been read recently, the result was as follows:

```
real    0m2.09s
user    0m0.03s
sys     0m0.74s
Ordinary Input:
      46416 page ins
      47132 page ins
Ordinary Output:
     146483 page outs
     147012 page outs
True Paging Output:
      4854 paging space page outs
```

```
4854 paging space page outs
True Paging Input:
2527 paging space page ins
2527 paging space page ins
```

The **time** command output confirms the existence of an I/O dependency. The increase in page ins shows the I/O necessary to satisfy the **cp** command. The increase in page outs indicates that the file is large enough to force the writing of dirty pages (not necessarily its own) from memory. The fact that there is no change in the cumulative paging-space-I/O counts confirms that the **cp** command does not build data structures large enough to overload the memory of the test machine.

The order in which this version of the **vmstatit** script reports I/O is intentional. Typical programs read file input and then write file output. Paging activity, on the other hand, typically begins with the writing out of a working-segment page that does not fit. The page is read back in only if the program tries to access it. The fact that the test system has experienced almost twice as many paging space page outs as paging space page ins since it was booted indicates that at least some of the programs that have been run on this system have stored data in memory that was not accessed again before the end of the program. Memory-Limited Programs provides more information. See also Chapter 7. Monitoring and Tuning Memory Use.

To show the effects of memory limitation on these statistics, the following example observes a given command in an environment of adequate memory (32 MB) and then artificially shrinks the system using the **rmss** command (see Assessing Memory Requirements Through the **rmss** Command). The command sequence

```
# cc -c ed.c
# vmstatit "cc -c ed.c" 2>results
```

first primes memory with the 7944-line source file and the executable file of the C compiler, then measures the I/O activity of the second execution:

```
real    0m7.76s
user    0m7.44s
sys     0m0.15s
Ordinary Input:
 57192 page ins
 57192 page ins
Ordinary Output:
165516 page outs
165553 page outs
True Paging Output:
10846 paging space page outs
10846 paging space page outs
True Paging Input:
 6409 paging space page ins
 6409 paging space page ins
```

Clearly, this is not I/O limited. There is not even any I/O necessary to read the source code. If we then issue the following command:

```
# rmss -c 8
```

to change the effective size of the machine to 8 MB, and perform the same sequence of commands, we get the following output:

```
real    0m9.87s
user    0m7.70s
sys     0m0.18s
Ordinary Input:
 57625 page ins
 57809 page ins
Ordinary Output:
165811 page outs
165882 page outs
```

```
True Paging Output:
  11010 paging space page outs
  11061 paging space page outs
True Paging Input:
  6623 paging space page ins
  6701 paging space page ins
```

The following symptoms of I/O dependency are present:

- Elapsed time longer than total CPU time
- Significant amounts of ordinary I/O on the *n*th execution of the command

The fact that the elapsed time is longer than in the memory-unconstrained situation, and the existence of significant amounts of paging-space I/O, make it clear that the compiler is being hampered by insufficient memory.

Note: This example illustrates the effects of memory constraint. No effort was made to minimize the use of memory by other processes, so the absolute size at which the compiler was forced to page in this environment does not constitute a meaningful measurement.

To avoid working with an artificially shrunken machine until the next restart, run

```
# rmss -r
```

to release back to the operating system the memory that the **rmss** command had sequestered, thus restoring the system to its normal capacity.

Managing Workload

When you have exhausted the program performance-improvement and system-tuning possibilities, and performance is still unsatisfactory at times, you have three choices:

- Let the situation remain as is.
- Upgrade the performance-limiting resource.
- Adopt workload-management techniques.

If you adopt the first approach, some of your less stoic users will experience increasing frustration and decreasing productivity. If you choose to upgrade, you will most likely have to justify the expenditure. That person will undoubtedly want to know if you have exhausted all possibilities with the current system, which means you need to investigate the possibilities of workload management.

Workload management simply means assessing the components of the workload to determine whether they are all needed as soon as possible. Usually, there is work that can wait for a while; for example, a report that is needed first thing in the morning. That report is equally useful when run at 3 a.m. as at 4 p.m. on the preceding day. The difference is that at 3 a.m. it uses CPU cycles and other resources that would otherwise be idle. Use the **at** or **crontab** command to request a program to run at a specific time or at regular intervals.

Similarly, some programs that do have to be run during the day can be run at reduced priority. They will take longer to complete, but they will be less in competition with really time-critical processes.

A related technique is moving work from one machine to another; for example, running a compilation on the machine where the source code resides. This kind of workload balancing requires more planning and monitoring, because reducing the load on the network and increasing the CPU load on a server might result in a net loss.

Starting with AIX 4.3.3, AIX Workload Manager (WLM) is provided as an integrated part of the operating system kernel. WLM is designed to give the system administrator greater control over how the scheduler

and virtual memory manager (VMM) allocate CPU and physical memory resources to processes. In AIX 5.1 and subsequent releases, disk usage can also be controlled by WLM. This can be used to prevent different classes of jobs from interfering with each other and to explicitly apply resources based on the requirements of different groups of users. For further information, see *Server Consolidation on RS/6000*.

Chapter 6. Monitoring and Tuning CPU Use

This chapter deals with techniques for detecting runaway or CPU-intensive programs and minimizing their adverse effect on performance.

Readers who are not familiar with CPU scheduling may want to look at Performance Overview of the CPU Scheduler before continuing.

The following sections cover the different aspects of CPU tuning:

- Monitoring CPU Use
- Using the time Command to Measure CPU Use
- Identifying CPU-Intensive Programs
- Using the tprof Program to Analyze Programs for CPU Use
- Using the pprof Command to Measure CPU usage of Kernel Threads
- Detecting Instruction Emulation with the emstat Tool
- Restructuring Executable Programs with the fdpr Program
- Controlling Contention for the CPU
- CPU-Efficient User ID Administration (The mkpasswd Command)

Monitoring CPU Use

The processing unit is one of the fastest components of the system. It is comparatively rare for a single program to keep the CPU 100 percent busy (that is, 0 percent idle and 0 percent wait) for more than a few seconds at a time. Even in heavily loaded multiuser systems, there are occasional 10 milliseconds (ms) periods that end with all threads in a wait state. If a monitor shows the CPU 100 percent busy for an extended period, there is a good chance that some program is in an infinite loop. Even if the program is "merely" expensive, rather than broken, it needs to be identified and dealt with.

The vmstat Command (CPU)

The first tool to use is the **vmstat** command, which quickly provides compact information about various system resources and their related performance problems. The **vmstat** command reports statistics about kernel threads in the run and wait queue, memory, paging, disks, interrupts, system calls, context switches, and CPU activity. The reported CPU activity is a percentage breakdown of user mode, system mode, idle time, and waits for disk I/O.

Note: If the **vmstat** command is used without any options or only with the interval and optionally, the count parameter, such as **vmstat 2 10**; then the first line of numbers is an average since system reboot.

As a CPU monitor, the **vmstat** command is superior to the **iostat** command in that its one-line-per-report output is easier to scan as it scrolls and there is less overhead involved if there are a lot of disks attached to the system. The following example can help you identify situations in which a program has run away or is too CPU-intensive to run in a multiuser environment.

```
# vmstat 2
kthr      memory          page          faults          cpu
-----
 r  b   avm    fre  re  pi  po  fr  sr  cy  in  sy  cs  us  sy  id  wa
1  0 22478  1677   0   0   0   0   0   0 188 1380 157 57 32   0 10
1  0 22506  1609   0   0   0   0   0   0 214 1476 186 48 37   0 16
0  0 22498  1582   0   0   0   0   0   0 248 1470 226 55 36   0  9

2  0 22534  1465   0   0   0   0   0   0 238  903 239 77 23   0  0
2  0 22534  1445   0   0   0   0   0   0 209 1142 205 72 28   0  0
```

```

2 0 22534 1426 0 0 0 0 0 0 189 1220 212 74 26 0 0
3 0 22534 1410 0 0 0 0 0 0 255 1704 268 70 30 0 0
2 1 22557 1365 0 0 0 0 0 0 383 977 216 72 28 0 0

2 0 22541 1356 0 0 0 0 0 0 237 1418 209 63 33 0 4
1 0 22524 1350 0 0 0 0 0 0 241 1348 179 52 32 0 16
1 0 22546 1293 0 0 0 0 0 0 217 1473 180 51 35 0 14

```

This output shows the effect of introducing a program in a tight loop to a busy multiuser system. The first three reports (the summary has been removed) show the system balanced at 50-55 percent user, 30-35 percent system, and 10-15 percent I/O wait. When the looping program begins, all available CPU cycles are consumed. Because the looping program does no I/O, it can absorb all of the cycles previously unused because of I/O wait. Worse, it represents a process that is always ready to take over the CPU when a useful process relinquishes it. Because the looping program has a priority equal to that of all other foreground processes, it will not necessarily have to give up the CPU when another process becomes dispatchable. The program runs for about 10 seconds (five reports), and then the activity reported by the **vmstat** command returns to a more normal pattern.

The CPU statistics can be somewhat distorted on systems with very high device-interrupt load. This situation is due to the fact that the tool samples on timer interrupts. The timer is the lowest priority device and therefore it can easily be preempted by other interrupts. To eliminate this distortion, operating system versions later than AIX 4.3.3 use a different method to sample the timer.

Note: For SMP systems the *us*, *sy*, *id* and *wa* columns are only averages over the processors (the **sar** command can report per-processor statistics). But keep in mind that the I/O wait statistic per processor is not really a processor-specific statistic; it is a global statistic. An I/O wait is distinguished from *idle time* only by the state of a pending I/O. If there is any pending disk I/O, and the processor is not busy, then it is an I/O wait time. AIX 4.3.3 and later contains an enhancement to the method used to compute the percentage of CPU time spent waiting on disk I/O (*wio* time). See Wait I/O Time Reporting for more details.

Optimum use would have the CPU working 100 percent of the time. This holds true in the case of a single-user system with no need to share the CPU. Generally, if *us* + *sy* time is below 90 percent, a single-user system is not considered CPU constrained. However, if *us* + *sy* time on a multiuser system exceeds 80 percent, the processes may spend time waiting in the run queue. Response time and throughput might suffer.

To check if the CPU is the bottleneck, consider the four *cpu* columns and the two *kthr* (kernel threads) columns in the **vmstat** report. It may also be worthwhile looking at the *faults* column:

- **cpu**

Percentage breakdown of CPU time usage during the interval. The *cpu* columns are as follows:

- **us**

The *us* column shows the percent of CPU time spent in user mode. A UNIX process can execute in either user mode or system (kernel) mode. When in user mode, a process executes within its application code and does not require kernel resources to perform computations, manage memory, or set variables.

- **sy**

The *sy* column details the percentage of time the CPU was executing a process in system mode. This includes CPU resource consumed by kernel processes (**kprocs**) and others that need access to kernel resources. If a process needs kernel resources, it must execute a system call and is thereby switched to system mode to make that resource available. For example, reading or writing of a file requires kernel resources to open the file, seek a specific location, and read or write data, unless memory mapped files are used.

- **id**

The `id` column shows the percentage of time which the CPU is idle, or waiting, without pending local disk I/O. If there are no threads available for execution (the run queue is empty), the system dispatches a process called **wait**. On an SMP system, one **wait** thread per processor can be dispatched. The report generated by the **ps** command (with the **-k** or **-g 0** option) identifies this as `kproc` or `wait`. On a uniprocessor system, the process ID (PID) usually is 516. SMP systems will have an idle `kproc` for each processor. If the **ps** report shows a high aggregate time for this thread, it means there were significant periods of time when no other thread was ready to run or waiting to be executed on the CPU. The system was therefore mostly *idle* and *waiting* for new tasks.

If there are no I/Os pending to a local disk, all time charged to **wait** is classified as *idle time*. In operating system version 4.3.2 and earlier, an access to remote disks (NFS-mounted disks) is treated as *idle time* (with a small amount of `sy` time to execute the NFS requests) because there is no pending I/O request to a local disk. With AIX 4.3.3 and later NFS goes through the buffer cache, and waits in those routines are accounted for in the `wa` statistics.

- **wa**

The `wa` column details the percentage of time the CPU was *idle* with pending local disk I/O (in AIX 4.3.3 and later this is also true for NFS-mounted disks). If there is at least one outstanding I/O to a disk when **wait** is running, the time is classified as waiting for I/O. Unless asynchronous I/O is being used by the process, an I/O request to disk causes the calling process to block (or sleep) until the request has been completed. Once an I/O request for a process completes, it is placed on the run queue. If the I/Os were completing faster, more CPU time could be used.

A `wa` value over 25 percent could indicate that the disk subsystem might not be balanced properly, or it might be the result of a disk-intensive workload.

For information on the change made to `wa`, see Wait I/O Time Reporting.

- **kthr**

Kernel threads placed on various queues per second over the sampling interval (state changes). The `kthr` columns are as follows:

- **r**

Average number of kernel threads waiting on the run queue per second; this means the average number of kernel threads that are in the run queue per second. This field indicates the number of threads that can be run. This value should be less than five for non-SMP systems. For SMP systems, this value should be less than:

$$5 \times (N_{\text{total}} - N_{\text{bind}})$$

Where N_{total} stands for total number of processors and N_{bind} for the number of processors which have been bound to processes, for example, with the **bindprocessor** command.

If this number increases rapidly, examine the applications. But systems may be also running fine with 10 to 15 threads on their run queue, depending on the thread tasks and the amount of time they run.

- **b**

Average number of kernel threads in the wait queue per second. These threads are waiting for resources or I/O. Threads are also located in the wait queue when waiting for one of their thread pages to be paged in. This value is usually near zero. But if the run-queue value increases, the wait-queue normally also increases. If threads are awakened simultaneously during a one second interval, the run-queue could be high but still show low CPU utilization if the threads go right back to sleep.

If processes are suspended due to memory load control, the blocked column (b) in the **vmstat** report indicates the increase in the number of threads rather than the run queue.

- **p**

For **vmstat -l** The number of threads waiting on actual physical I/O per second.

- **faults**

Information about process control, such as trap and interrupt rate. The `faults` columns are as follows:

- **in**

Number of device interrupts per second observed in the interval. Additional information can be found in Assessing Disk Performance with the `vmstat` Command.

– **sy**

The number of system calls per second observed in the interval. Resources are available to user processes through well-defined system calls. These calls instruct the kernel to perform operations for the calling process and exchange data between the kernel and the process. Because workloads and applications vary widely, and different calls perform different functions, it is impossible to define how many system calls per-second are too many. But typically, when the `sy` column raises over 10000 calls per second on a uniprocessor, further investigations is called for (on an SMP system the number is 10000 calls per second per processor). One reason could be “polling” subroutines like the `select()` subroutine. For this column, it is advisable to have a baseline measurement that gives a count for a normal `sy` value.

– **cs**

Number of context switches per second observed in the interval. The physical CPU resource is subdivided into logical time slices of 10 milliseconds each. Assuming a thread is scheduled for execution, it will run until its time slice expires, until it is preempted, or until it voluntarily gives up control of the CPU. When another thread is given control of the CPU, the context or working environment of the previous thread must be saved and the context of the current thread must be loaded. The operating system has a very efficient context switching procedure, so each switch is inexpensive in terms of resources. Any significant increase in context switches, such as when `cs` is a lot higher than the disk I/O and network packet rate, should be cause for further investigation.

The `iostat` Command

The `iostat` command is the fastest way to get a first impression, whether or not the system has a disk I/O-bound performance problem (see Assessing Disk Performance with the `iostat` Command). The tool also reports CPU statistics.

The following example shows a part of an `iostat` command output. The first stanza shows the summary statistic since system startup.

```
# iostat -t 2 6
tty:      tin      tout  avg-cpu:  % user   % sys    % idle   % iowait
          0.0      0.8      8.4     2.6     88.5     0.5
          0.0     80.2     4.5     3.0     92.1     0.5
          0.0     40.5     7.0     4.0     89.0     0.0
          0.0     40.5     9.0     2.5     88.5     0.0
          0.0     40.5     7.5     1.0     91.5     0.0
          0.0     40.5    10.0     3.5     80.5     6.0
```

The CPU statistics columns (`% user`, `% sys`, `% idle`, and `% iowait`) provide a breakdown of CPU usage. This information is also reported in the `vmstat` command output in the columns labeled `us`, `sy`, `id`, and `wa`. For a detailed explanation for the values, see The `vmstat` Command. Also note the change made to `%iowait` described in Wait I/O Time Reporting.

The `sar` Command

The `sar` command gathers statistical data about the system. Though it can be used to gather some useful data regarding system performance, the `sar` command can increase the system load that can exacerbate a pre-existing performance problem if the sampling frequency is high. But compared to the accounting package, the `sar` command is less intrusive. The system maintains a series of system activity counters which record various activities and provide the data that the `sar` command reports. The `sar` command does not cause these counters to be updated or used; this is done automatically regardless of whether or not the `sar` command runs. It merely extracts the data in the counters and saves it, based on the sampling rate and number of samples specified to the `sar` command.

With its numerous options, the `sar` command provides queuing, paging, TTY, and many other statistics. One important feature of the `sar` command is that it reports either systemwide (global among all

processors) CPU statistics (which are calculated as averages for values expressed as percentages, and as sums otherwise), or it reports statistics for each individual processor. Therefore, this command is particularly useful on SMP systems.

There are three situations to use the **sar** command:

Real-time sampling and display

To collect and display system statistic reports immediately, use the following command:

```
# sar -u 2 5
```

```
AIX texmex 3 4 000691854C00 01/27/00

17:58:15   %usr   %sys   %wio   %idle
17:58:17     43     9      1     46
17:58:19     35    17      3     45
17:58:21     36    22     20     23
17:58:23     21    17      0     63
17:58:25     85    12      3      0

Average     44     15      5     35
```

This example is from a single user workstation and shows the CPU utilization.

Display previously captured data

The **-o** and **-f** options (write and read to/from user given data files) allow you to visualize the behavior of your machine in two independent steps. This consumes less resources during the problem-reproduction period. You can use a separate machine to analyze the data by transferring the file because the collected binary file keeps all data the **sar** command needs.

```
# sar -o /tmp/sar.out 2 5 > /dev/null
```

The above command runs the **sar** command in the background, collects system activity data at 2-second intervals for 5 intervals, and stores the (unformatted) **sar** data in the **/tmp/sar.out** file. The redirection of standard output is used to avoid a screen output.

The following command extracts CPU information from the file and outputs a formatted report to standard output:

```
# sar -f/tmp/sar.out
```

```
AIX texmex 3 4 000691854C00 01/27/00

18:10:18   %usr   %sys   %wio   %idle
18:10:20     9      2      0     88
18:10:22    13     10     0     76
18:10:24    37      4      0     59
18:10:26     8      2      0     90
18:10:28    20      3      0     77

Average     18      4      0     78
```

The captured binary data file keeps all information needed for the reports. Every possible **sar** report could therefore be investigated. This also allows to display the processor-specific information of an SMP system on a single processor system.

System activity accounting via cron daemon

The **sar** command calls a process named **sadc** to access system data. Two shell scripts (**/usr/lib/sa/sa1** and **/usr/lib/sa/sa2**) are structured to be run by the **cron** daemon and provide daily statistics and reports. Sample stanzas are included (but commented out) in the **/var/spool/cron/crontabs/adm** crontab file to specify when the **cron** daemon should run the shell scripts.

The following lines show a modified crontab for the adm user. Only the comment characters for the data collections were removed:

```

=====
#      SYSTEM ACTIVITY REPORTS
# 8am-5pm activity reports every 20 mins during weekdays.
# activity reports every an hour on Saturday and Sunday.
# 6pm-7am activity reports every an hour during weekdays.
# Daily summary prepared at 18:05.
=====
0 8-17 * * 1-5 /usr/lib/sa/sa1 1200 3 &
0 * * * 0,6 /usr/lib/sa/sa1 &
0 18-7 * * 1-5 /usr/lib/sa/sa1 &
5 18 * * 1-5 /usr/lib/sa/sa2 -s 8:00 -e 18:01 -i 3600 -ubcwyaqvm &
=====

```

Collection of data in this manner is useful to characterize system usage over a period of time and to determine peak usage hours.

Useful CPU Options: The most useful CPU-related options for the **sar** command are:

- **sar -P**

The **-P** option reports per-processor statistics for the specified processors. By specifying the **ALL** keyword, statistics for each individual processor and an average for all processors is reported. Of the flags which specify the statistics to be reported, only the **-a**, **-c**, **-m**, **-u**, and **-w** flags are meaningful with the **-P** flag.

The following example shows the per-processor statistic while a CPU-bound program was running on processor number 0:

```

# sar -P ALL 2 3

AIX rugby 3 4 00058033A100    01/27/00

17:30:50 cpu      %usr    %sys    %wio    %idle
17:30:52 0         8       92       0        0
          1         0        4        0       96
          2         0        1        0       99
          3         0        0        0      100
          -         2       24        0       74
17:30:54 0        12      88        0        0
          1         0        3        0       97
          2         0        1        0       99
          3         0        0        0      100
          -         3       23        0       74
17:30:56 0        11      89        0        0
          1         0        3        0       97
          2         0        0        0      100
          3         0        0        0      100
          -         3       23        0       74

Average 0         10      90        0        0
          1         0        4        0       96
          2         0        1        0       99
          3         0        0        0      100
          -         3       24        0       74

```

The last line of every stanza, which starts with a dash (-) in the **cpu** column, is the average for all processors. An average (-) line displays only if the **-P ALL** option is used. It is removed if processors are specified. The last stanza, labeled with the word **Average** instead of a time stamp, keeps the averages for the processor-specific rows over all stanzas.

The following example shows the **vmstat** output during this time:

```
# vmstat 2 5
kthr      memory          page          faults          cpu
-----
 r b   avm  fre  re pi po fr sr  cy in  sy cs us sy id wa
0 0 5636 16054 0 0 0 0 0 0 116 266 5 0 1 99 0
1 1 5733 15931 0 0 0 0 0 0 476 50781 35 2 27 70 0
1 1 5733 15930 0 0 0 0 0 0 476 49437 27 2 24 74 0
1 1 5733 15930 0 0 0 0 0 0 473 48923 31 3 23 74 0
1 1 5733 15930 0 0 0 0 0 0 466 49383 27 3 23 74 0
```

The first numbered line is the summary since startup of the system. The second line reflects the start of the **sar** command, and with the third row, the reports are comparable. The **vmstat** command can only display the average CPU utilization over all processors. This is comparable with the dashed (-) rows from the CPU utilization output from the **sar** command.

- **sar -u**

This displays the CPU utilization. It is the default if no other flag is specified. It shows the same information as the CPU statistics of the **vmstat** or **iostat** commands.

During the following example, a copy command was started:

```
# sar -u -P ALL 1 5

AIX rugby 3 4 00058033A100    10/07/99

13:33:42 cpu      %usr      %sys      %wio      %idle
13:33:43  0          0          0          0         100
          1          0          0          0         100
          2          0          0          0         100
          3          0          0          0         100
          -          0          0          0         100
13:33:44  0          2          66          0          32
          1          0          1          0          99
          2          0          0          0         100
          3          0          1          0          99
          -          0          17          0          82
13:33:45  0          1          52          44          3
          1          0          1          0          99
          2          0          4          0          96
          3          0          0          0         100
          -          0          14          11          74
13:33:46  0          0          8          91          1
          1          0          0          0         100
          2          0          0          0         100
          3          0          1          0          99
          -          0          2          23          75
13:33:47  0          0          7          93          0
          1          0          0          0         100
          2          0          1          0          99
          3          0          0          0         100
          -          0          2          23          75

Average  0          1          27          46          27
          1          0          0          0         100
          2          0          1          0          99
          3          0          0          0         100
          -          0          7          11          81
```

The **cp** command is working on processor number 0, and the three other processors are idle. This reflects the change with operating system version 4.3.3 (see Wait I/O Time Reporting).

- **sar -c**

The **-c** option shows the system call rate.

```
# sar -c 1 3
19:28:25 scall/s sread/s swrit/s fork/s exec/s rchar/s wchar/s
19:28:26      134      36      1      0.00      0.00 2691306      1517
```

19:28:27	46	34	1	0.00	0.00	2716922	1531
19:28:28	46	34	1	0.00	0.00	2716922	1531
Average	75	35	1	0.00	0.00	2708329	1527

While the **vmstat** command shows system call rates as well, the **sar** command can also show if these system calls are **read()**, **write()**, **fork()**, **exec()**, and others. Pay particular attention to the fork/s column. If this is high, then further investigation might be needed using the accounting utilities, the **trace** command, or the **tprof** command.

- **sar -q**

The **-q** option shows the run-queue size and the swap-queue size.

```
# sar -q 5 3
```

```
19:31:42 runq-sz %runocc swpq-sz %swpocc
19:31:47      1.0      100      1.0      100
19:31:52      2.0      100      1.0      100
19:31:57      1.0      100      1.0      100

Average      1.3       95       1.0       95
```

runq-sz

The average run-queue size, average number of threads running, and the percentage of time that the run queue was occupied (the % field is subject to error).

swpq-sz

The average number of threads waiting for a page fault resolution and the % of time that the swap queue was occupied. (The % field is subject to error.)

The **-q** option can indicate whether you have too many jobs running (**runq-sz**) or have a potential paging bottleneck. In a highly transactional system, for example Enterprise Resource Planning (ERP), the run queue can be in the hundreds, because each transaction uses small amounts of CPU time. If paging is the problem, run the **vmstat** command. High I/O wait indicates that there is significant competing disk activity or excessive paging due to insufficient memory.

The xmpperf Program

Using the **xmpperf** program displays CPU use as a moving skyline chart. The **xmpperf** program is described in detail in the *Performance Toolbox Version 2 and 3 for AIX: Guide and Reference*.

Using the time Command to Measure CPU Use

Use the **time** command to understand the performance characteristics of a single program and its synchronous children. It reports the *real* time, that is the elapsed time from beginning to end of the program. It also reports the amount of CPU time used by the program. The CPU time is divided into user and sys. The user value is the time used by the program itself and any library subroutines it calls. The sys value is the time used by system calls invoked by the program (directly or indirectly).

The sum of user + sys is the total direct CPU cost of executing the program. This does not include the CPU costs of parts of the kernel that can be said to run on behalf of the program, but which do not actually run on its thread. For example, the cost of stealing page frames to replace the page frames taken from the free list when the program started is not reported as part of the program's CPU consumption.

On a uniprocessor, the difference between the real time and the total CPU time, that is:

```
real - (user + sys)
```

is the sum of all of the factors that can delay the program, plus the program's own unattributed costs. On an SMP, an approximation would be as follows:

```
real * number_of_processors - (user + sys)
```

In approximately the order of diminishing size, the factors can be:

- I/O required to bring in the program's text and data
- I/O required to acquire real memory for the program's use
- CPU time consumed by other programs
- CPU time consumed by the operating system

In the following example, the program used in the preceding section has been compiled with **-O3** to make it run more quickly. There is very little difference between the real (wall-clock) time required to run the program and the sum of its user and system CPU times. The program is getting all the time it wants, probably at the expense of other programs in the system.

```
# time looper
real    0m3.58s
user    0m3.16s
sys     0m0.04s
```

In the next example, we run the program at a less favorable priority by adding 10 to its nice value. It takes almost twice as long to run, but other programs are also getting a chance to do their work:

```
# time nice -n 10 looper
real    0m6.54s
user    0m3.17s
sys     0m0.03s
```

Note that we placed the **nice** command within the **time** command, rather than the reverse. If we had entered

```
# nice -n 10 time looper
```

we would have gotten a different **time** command (**/usr/bin/time**) with a lower-precision report, rather than the version of the **time** command we have been using, which is built into the **ksh** shell. If the **time** command comes first, you get the built-in version, unless you specify the fully qualified name of **/usr/bin/time**. If the **time** command is invoked from another command, you get **/usr/bin/time**.

time and timex Cautions

Take several considerations into account when you use either the **time** or the **timex** command:

- The use of the **/usr/bin/time** and **/usr/bin/timex** commands is not recommended. When possible, use the time subcommand of the Korn or C shell.
- The **timex -s** command uses the **sar** command to acquire additional statistics. Because the **sar** command is intrusive, the **timex -s** command is also. Especially for brief runs, the data reported by the **timex -s** command may not precisely reflect the behavior of a program in an unmonitored system.
- Because of the length of the system clock tick (10 milliseconds) and the rules used by the scheduler in attributing CPU time use to threads, the results of the **time** command are not completely deterministic. Because the time is sampled, there is a certain amount of unavoidable variation between successive runs. This variation is in terms of clock ticks. The shorter the run time of the program, the larger the variation as a percentage of the reported result (see Appendix C. Accessing the Processor Timer).
- Use of the **time** or **timex** command (whether from **/usr/bin** or through the built-in shell **time** function) to measure the user or system time of a sequence of commands connected by pipes, entered on the command line, is not recommended. One potential problem is that syntax oversights can cause the **time** command to measure only one of the commands, without any indication of a user error. The syntax is technically correct; it just does not produce the answer that the user intended.
- Although the **time** command syntax did not change, its output takes on a new meaning in an SMP environment:

On an SMP the real, or elapsed time may be smaller than the user time of a process. The user time is now the sum of all the times spent by the threads or the process on all processors.

If a process has four threads, running it on a uniprocessor (UP) system shows that the real time is greater than the user time:

```
# time 4threadedprog
real    0m11.70s
user    0m11.09s
sys     0m0.08s
```

Running it on a 4-way SMP system could show that the real time is only about 1/4 of the user time. The following output shows that the multithreaded process distributed its workload on several processors and improved its real execution time. The throughput of the system was therefore increased.

```
# time 4threadedprog
real    0m3.40s
user    0m9.81s
sys     0m0.09s
```

Identifying CPU-Intensive Programs

To locate the processes dominating CPU usage, there are two standard tools, the **ps** command and the **acctcom** command. Another tool to use is the **topas** monitor, which is described in Using the topas Monitor.

Using the ps Command

The **ps** command is a flexible tool for identifying the programs that are running on the system and the resources they are using. It displays statistics and status information about processes on the system, such as process or thread ID, I/O activity, CPU and memory utilization. In this chapter, we discuss only the options and output fields that are relevant for CPU.

Three of the possible **ps** output columns report CPU use, each in a different way.

Column

Value Is:

C Recently used CPU time for the process (in units of clock ticks).

TIME Total CPU time used by the process since it started (in units of minutes and seconds).

%CPU Total CPU time used by the process since it started, divided by the elapsed time since the process started. This is a measure of the CPU dependence of the program.

CPU Intensive

The following shell script:

```
# ps -ef | egrep -v "STIME|$LOGNAME" | sort +3 -r | head -n 15
```

is a tool for focusing on the highest recently used CPU-intensive user processes in the system (the header line has been reinserted for clarity):

```
UID  PID  PPID  C   STIME  TTY  TIME CMD
mary 45742 54702 120 15:19:05 pts/29 0:02 ./looper
root 52122 1 11 15:32:33 pts/31 58:39 xhogger
root 4250 1 3 15:32:33 pts/31 26:03 xmconsole allcon
root 38812 4250 1 15:32:34 pts/31 8:58 xmconstats 0 3 30
root 27036 6864 1 15:18:35 - 0:00 rlogind
root 47418 25926 0 17:04:26 - 0:00 coelogin <d29dbms:0>
bick 37652 43538 0 16:58:40 pts/4 0:00 /bin/ksh
bick 43538 1 0 16:58:38 - 0:07 aixterm
luc 60062 27036 0 15:18:35 pts/18 0:00 -ksh
```

Recent CPU use is the fourth column (C). The looping program's process easily heads the list. Observe that the C value may understate the looping process' CPU usage, because the scheduler stops counting at 120.

CPU Time Ratio

The **ps** command, run periodically, displays the CPU time under the TIME column and the ratio of CPU time to real time under the %CPU column. Look for the processes that dominate usage. The **au** and **v** options give similar information on user processes. The options **aux** and **vg** display both user and system processes.

The following example is taken from a four-way SMP system:

```
# ps au
USER      PID %CPU %MEM  SZ  RSS  TTY STAT   STIME  TIME  COMMAND
root    19048 24.6  0.0   28   44 pts/1 A   13:53:00 2:16 /tmp/cpubound
root    19388  0.0  0.0  372  460 pts/1 A       Feb 20 0:02 -ksh
root    15348  0.0  0.0  372  460 pts/4 A       Feb 20 0:01 -ksh
root    20418  0.0  0.0  368  452 pts/3 A       Feb 20 0:01 -ksh
root    16178  0.0  0.0  292  364    0 A       Feb 19 0:00 /usr/sbin/getty
root    16780  0.0  0.0  364  392 pts/2 A       Feb 19 0:00 -ksh
root    18516  0.0  0.0  360  412 pts/0 A       Feb 20 0:00 -ksh
root    15746  0.0  0.0  212  268 pts/1 A   13:55:18 0:00 ps au
```

The %CPU is the percentage of CPU time that has been allocated to that process since the process was started. It is calculated as follows:

```
(process CPU time / process duration) * 100
```

Imagine two processes: The first starts and runs five seconds, but does not finish; then the second starts and runs five seconds but does not finish. The **ps** command would now show 50 percent %CPU for the first process (five seconds CPU for 10 seconds of elapsed time) and 100 percent for the second (five seconds CPU for five seconds of elapsed time).

On an SMP, this value is divided by the number of available CPUs on the system. Looking back at the previous example, this is the reason why the %CPU value for the **cpubound** process will never exceed 25, because the example is run on a four-way processor system. The **cpubound** process uses 100 percent of one processor, but the %CPU value is divided by the number of available CPUs.

The THREAD Option

The **ps** command can display threads and the CPUs that threads or processes are bound to by using the **ps -mo THREAD** command. The following is an example:

```
# ps -mo THREAD
USER PID  PPID TID  ST CP PRI SC WCHAN F      TT    BND COMMAND
root 20918 20660 -      A  0 60 1 -      240001 pts/1 -   -ksh
-    -    -    20005 S  0 60 1 -      400    -    -   -
```

The TID column shows the thread ID, the BND column shows processes and threads bound to a processor.

It is normal to see a process named **kproc** (PID of 516 in operating system version 4) using CPU time. When there are no threads that can be run during a time slice, the scheduler assigns the CPU time for that time slice to this kernel process (**kproc**), which is known as the *idle* or *wait* **kproc**. SMP systems will have an *idle* **kproc** for each processor. With operating system versions later than AIX 4.3.3 the name shown in the output is *wait*.

For complete details about the **ps** command, see the *AIX 5L Version 5.1 Commands Reference*.

Using the acctcom Command

The **acctcom** command displays historical data on CPU usage if the accounting system is activated. Starting the accounting system puts a measurable overhead on the system. Therefore, activate accounting only if absolutely needed. To activate the accounting system, do the following:

1. Create an empty accounting file:

```
# touch acctfile
```

2. Turn on accounting:

```
# /usr/sbin/acct/accton acctfile
```

3. Allow accounting to run for a while and then turn off accounting:

```
# /usr/sbin/acct/accton
```

4. Display what accounting captured, as follows:

```
# /usr/sbin/acct/acctcom acctfile
```

COMMAND NAME	USER	TTYNAME	START TIME	END TIME	REAL (SECS)	CPU (SECS)	MEAN SIZE(K)
#accton	root	pts/2	19:57:18	19:57:18	0.02	0.02	184.00
#ps	root	pts/2	19:57:19	19:57:19	0.19	0.17	35.00
#ls	root	pts/2	19:57:20	19:57:20	0.09	0.03	109.00
#ps	root	pts/2	19:57:22	19:57:22	0.19	0.17	34.00
#accton	root	pts/2	20:04:17	20:04:17	0.00	0.00	0.00
#who	root	pts/2	20:04:19	20:04:19	0.02	0.02	0.00

If you reuse the same file, you can see when the newer processes were started by looking for the **accton** process (this was the process used to turn off accounting the first time).

Using the tprof Program to Analyze Programs for CPU Use

The typical program execution is a variable mixture of application code, library subroutines, and kernel services. Frequently, a program that has not yet been tuned is found to expend most of its CPU cycles in a few statements or subroutines. Often these *hot spots* are a surprise to the programmer. They often can be considered performance problems. Use the **tprof** command to pinpoint any hot spots (for additional information see The tprof Command). The **tprof** command can profile any program produced by one of the compilers: C, C++, and FORTRAN.

To determine whether the **tprof** program is installed and available, run the following command:

```
# ls1pp -lI perfagent.tools
```

The raw data for the **tprof** program is obtained through the trace facility (see Chapter 12. Analyzing Performance with the Trace Facility). When a program is profiled, the trace facility is activated and instructed to collect data from the trace hook (hook ID 234) that records the contents of the Instruction Address Register when a system-clock interrupt occurs (100 times a second per processor). Several other trace hooks are also activated to allow the **tprof** program to track process and dispatch activity. The trace records are not written to a disk file; they are written to a pipe that is read by a program that builds a table of the unique program addresses that have been encountered and the number of times each one occurred. When the workload being profiled is complete, the table of addresses and their occurrence counts is written to disk. The data-reduction component of the **tprof** program then correlates the instruction addresses that were encountered with the ranges of addresses occupied by the various programs and reports the distribution of address occurrences (*ticks*) across the programs involved in the workload.

The distribution of ticks is roughly proportional to the CPU time spent in each program (10 milliseconds per tick). After the high-use programs have been identified, the programmer can take action to restructure their hot spots or minimize their use.

A tprof Example

The following C program initializes each byte of a large array of integers to 0x01, increments each integer by a random constant, and prints out a randomly selected integer. The program is representative of programs that process large arrays.

```
/* Array Incrementer -- Version 1 */
#include <stdlib.h>
#define Asize 1024
#define RowDim InnerIndex
#define ColDim OuterIndex
main()
{
```

```

int Increment;
int OuterIndex;
int InnerIndex;
int big [ASize][ASize];
/* initialize every byte of the array to 0x01 */
for(OuterIndex=0; OuterIndex<ASize; OuterIndex++)
{
    for (InnerIndex=0; InnerIndex<ASize; InnerIndex++)
        big[RowDim][ColDim] = 0x01010101;
}
Increment = rand();
/* increment every element in the array */
for(OuterIndex=0; OuterIndex<ASize; OuterIndex++)
{
    for (InnerIndex=0; InnerIndex<ASize; InnerIndex++)
    {
        big[RowDim][ColDim] += Increment;
        if (big[RowDim][ColDim] < 0)
            printf("Negative number. %d\n",big[RowDim][ColDim]);
    }
}
printf("Version 1 Check Num: %d\n",
        big[rand()%ASize][rand()%ASize]);
return(0);
}

```

The program was compiled with the following command:

```
# xlc -g version1.c -o version1
```

The **-g** parameter causes the C compiler to generate the object module with symbolic debugging information for use by the **tprof** program. Although the **tprof** program can profile optimized modules, the **-O** parameter has been omitted to make the line numbers that the **tprof** program uses more precise. When the C compiler is optimizing, it often does enough rearrangement of code to make the output of the **tprof** program harder to interpret. On the test system, this program runs in about 5.97 seconds of elapsed time, of which more than 5.9 seconds is user CPU time. The program clearly meets its objective of being CPU-limited.

We can profile the program with the following command (include the **-m** option on operating system versions later than AIX 4.3.3):

```
# tprof -p version1 -x version1
```

A file called **__version1.all** (shown below) is created. It reports how many CPU ticks each of the programs involved in the execution consumed.

```

The first section of the **tprof** report shows the number of ticks consumed by, or on behalf of, each process. The program **version1** used 763 ticks itself, and 30 ticks occurred in the kernel on behalf of **version1**'s process. Two processes running the Bourne shell were involved in the execution of **version1**. Four processes were running **tprof**-related code. The **init** process, the **sync** daemon, an **rlogin** process, and one other process accounted for 14 ticks.

Remember that the program associated with a given numerical process ID changes with each **exec()** subroutine call. If one application program uses the **exec()** subroutine to execute another, both program names will appear in the **tprof** output associated with the same process ID.

The second section of the report summarizes the results by program, regardless of process ID. It shows the number (FREQ) of different processes that ran each program at some point.

The third section breaks down the user ticks associated with the executable program being profiled. It reports the number of ticks used by each function in the executable program, and the percentage of the total run's CPU ticks (823) that each function's ticks represent.

Up to this point, none of the **tprof** processing has required access to the specially compiled version of the program. You could have done the preceding analysis on a program for which you did not have access to the source code.

It is clear from this report that the main CPU consumption (92.7 percent) is in the program itself, not in the kernel nor in library subroutines that the program uses. You must examine the program itself more closely.

Because you compiled **version1.c** with the **-g** option, the object file contains information that relates offsets in the program text to lines of source code. Consequently, the **tprof** program created an annotated version of the source file **version1.c**, called **__t.version1.c**, based on the offsets and line number information in the object module. The first column is the line number. The second column is the number of times the trace hook reported that the timer interrupt occurred while the system was executing one of the instructions associated with that line.

Ticks Profile for main in version1.c

```

Line  Ticks  Source
14    34    for(OuterIndex=0; OuterIndex<Asize; OuterIndex++)
15    -    {
16    40    for (InnerIndex=0; InnerIndex<Asize; InnerIndex++)
17    261    big[RowDim][ColDim] = 0x01010101;
18    -    }

33     -     return(0);
34     -     }

```

763 Total Ticks for main in version1.c

This file shows that the largest numbers of ticks are associated with accessing elements of the array `big`, so you should be able to enhance performance significantly by concentrating on the inner for loops. The first (initialization) for loop is a case of inefficient programming, because it initializes the array one element at a time. If you were setting the array to 0, use the `bzero()` subroutine. Because you are setting each byte to a specific character, use the `memset()` subroutine to replace the first for loop. (The efficient `bzero()` and `memset()` functions, like the `str*` functions, are written in assembler language and use hardware instructions that have no direct equivalent in the C language.)

You must access the array one element at a time to increment the values, but ensure that the pattern of memory reference is to consecutive addresses, to maximize cache use. In this case, you have the row dimension changing faster than the column dimension. Because C arrays are arranged in row-major order, you are skipping over a complete row with each successive memory reference. Because the rows are 1024 integers long (4096 bytes), you are changing pages on every reference. The size of the array greatly exceeds both the data cache and data Translation Lookaside Buffer (TLB) capacities, so you have written a program for maximum cache and TLB thrashing. To fix this problem, transpose the two `#define` statements to reverse the values of `RowDim` and `ColDim`.

The unoptimized form of the resulting program (`version2.c`) consumes about 2.7 CPU seconds, compared with 7.9 CPU seconds for program `version1`.

The following file, `__t.version2.c`, is the result of a `tprof` run against the unoptimized form:

Ticks Profile for main in version2.c

Line	Ticks	Source
15	-	<code>memset(big,0x01,sizeof(big));</code>
16	-	<code>Increment = rand();</code>
17	-	
18	-	<code>/* increment in memory order */</code>
19	60	<code>for(OuterIndex=0; OuterIndex<Asize; OuterIndex++)</code>
20	-	<code>{</code>
21	-	<code>for (InnerIndex=0; InnerIndex<Asize; InnerIndex++)</code>
22	-	<code>{</code>
23	67	<code>big[RowDim][ColDim] += Increment;</code>
24	60	<code>if (big[RowDim][ColDim] < 0)</code>
25	43	<code>printf("Negative number. %d\n",big[RowDim][ColDim]);</code>
26	-	<code>}</code>
27	-	<code>}</code>
28	-	<code>printf("Version 2 Check Num: %d\n",</code>
29	-	<code>big[rand()%Asize][rand()%Asize]);</code>
30	-	<code>return(0);</code>
31	-	<code>}</code>

230 Total Ticks for main in version2.c

By knowing its CPU use pattern, you have improved the CPU speed of this program by a factor of almost three, for the unoptimized case. When you compile `version1.c` and `version2.c` with optimization and compare their performance, the "before and after" improvement due to the changes is a factor of 7.

In many cases, most of a program's CPU use will occur in the library subroutines it uses rather than in the program itself. If you take `version2.c` and remove the conditional test on line 24 and the `printf()` entry on line 28, to create a `version3.c` that reads as follows:

```

#include <string.h>
#include <stdlib.h>
#define Asize 256
#define RowDim OuterIndex
#define ColDim InnerIndex

main()
{
    int Increment;
    int OuterIndex;
    int InnerIndex;
    int big [Asize][Asize];

    /* Initialize every byte to 0x01 */
    memset(big,0x01,sizeof(big));
    Increment = rand();
    /* increment in memory order */
    for(OuterIndex=0; OuterIndex<Asize; OuterIndex++)
    {
        for (InnerIndex=0; InnerIndex<Asize; InnerIndex++)
        {
            big[RowDim][ColDim] += Increment;
            printf("RowDim=%d, ColDim=%d, Number=%d\n",
                RowDim, ColDim, big[RowDim][ColDim]);
        }
    }
    return(0);
}

```

the execution time becomes dominated by the **printf()** statement. The command:

```
# tprof -v -s -k -p version3 -x version3 >/dev/null
```

produces a **__version3.all** that includes profiling data for the kernel and the shared subroutine library **libc.a** (the only shared library this program uses):

._ioctl	1	0.1	ioctl.c	57576	240

This report confirms that most of the ticks are being used by the shared libraries (**libc.a** in this case). The profile of **libc.a** shows that most of those ticks are being consumed by the **_doprnt()** subroutine.

The **_doprnt()** subroutine is the processing module for the **printf()**, **sprintf()**, and other subroutines. With a simple change, you have increased the run time from 2.7 seconds to 8.6 seconds, and the formatted printing now consumes about 60 percent of the CPU time. This illustrates why formatting should be used judiciously. The performance of the **_doprnt()** subroutine is also affected by the locale. See Appendix E. National Language Support: Locale versus Speed. These tests were run in the C locale, which is the most efficient.

Offline Processing with the tprof Command

The **-i Trace_File** flag allows for offline processing by the **tprof** command of trace data files created by the system **trace** command. The **-n** flag allows you to specify a *Gennames_File* to be used when processing an offline file. These flags are useful when it is necessary to postprocess a trace file from a remote machine or perform the trace data collection at one time and postprocess it at another time. In this case **-n** with a *Gennames_File* must be used from the machine that the trace came from. The flags are also useful when system loading is high and trace hooks are being missed by the **tprof** command. The offline option relieves this problem.

Trace hooks relevant to the **tprof** command must be collected by the **trace** command and are specified by the **trace -j** flag. The **gennames** command is then executed to collect additional information for the **tprof** command. After the **trace** and **gennames Ggennames_File** commands have executed, the **trcrpt -r** command must be executed on the trace logfile and redirected to another file. At this point an adjusted trace logfile and a *Gennames_File* is input to the **tprof** command.

For example:

```
# trace -af -T 1000000 -L 10000000 -o trace.out -j 000,001,002,003,005,006,234,106,10C,134,139,00A,465
# workload
# trcoff
# gennames > gennames.out
# trcstop
# trcrpt -r trace.out > trace.rpt
```

Next run the **tprof** command with at least the **-i** and **-n** flags, as follows:

```
# tprof -i trace.rpt -n gennames.out -s -k -e
```

On systems with many CPUs, it is better to run the **trace** and **trcrpt** commands with the **-C all** flag (see Formatting a Report from trace -C Output).

Using the pprof Command to Measure CPU usage of Kernel Threads

The **pprof** command reports CPU usage on all kernel threads running within an interval using the trace utility. The raw process information is saved to **pprof.flow** and five reports are generated. If no flags are specified, all reports are generated.

To determine whether the **pprof** program (available with AIX 4.3.3 and later) is installed and available, run the following command:

```
# ls|pp -lI perfagent.tools
```

The types of reports are as follows:

pprof.cpu

Lists all kernel level threads sorted by actual CPU time. Contains: Process Name, Process ID, Parent Process ID, Process State at Beginning and End, Thread ID, Parent Thread ID, Actual CPU Time, Start Time, Stop Time, Stop - Start.

pprof.famcpu

Lists the information for all families (processes with a common ancestor). The Process Name and Process ID for the family is not necessarily the ancestor. Contains: Start Time, Process Name, Process ID, Number of Threads, Total CPU Time.

pprof.famind

Lists all processes grouped by families (processes with a common ancestor). Child process names are indented with respect to the parent. Contains: Start Time, Stop Time, Actual CPU Time, Process ID, Parent Process ID, Thread ID, Parent Thread ID, Process State at Beginning and End, Level, Process Name.

pprof.namecpu

Lists information about each type of kernel thread (all executable with the same name). Contains: Process Name, Number of Threads, CPU Time, % of Total CPU Time.

pprof.start

Lists all kernel threads sorted by start time that were dispatched during the the **pprof** command interval. Contains: Process Name, Process ID, Parent Process ID, Process State Beginning and End, Thread ID, Parent Thread ID, Actual CPU Time, Start Time, Stop Time, Stop - Start.

Following is a sample **pprof.namecpu** file that was generated by running the **tthreads32** program, which forks off four threads, which in turn each fork off a process of their own. These processes then execute several **ksh** and **sleep** programs:

```

Detecting Instruction Emulation with the emstat Tool

The POWER-based architecture deleted (that is, no longer supports) 35 POWER instructions (5 for the PowerPC 601 RISC Microprocessor "bridge"). To maintain compatibility with older binaries (which may contain these deleted instructions) the AIX Version 4 kernel includes emulation routines that provide support for the deleted instructions. Attempting to execute a deleted instruction results in an illegal instruction exception. The kernel decodes the illegal instruction, and if it is a deleted instruction, the kernel runs an emulation routine that functionally emulates the instruction.

However, depending upon the execution frequency of deleted instructions and the deleted instruction emulation path lengths, emulation can result in varying degrees of performance degradation due to kernel context switch and instruction emulation overhead. Even a very small percentage of emulation might result in a big performance difference. The following table shows estimated instruction path lengths for several of the deleted instructions:

Instruction	Emulated in	Estimated Path Length (instructions)
abs	assembler	117
doz	assembler	120
mul	assembler	127
rlmi	C	425
sle	C	447
clf	C	542
div	C	1079

Most emulation problems are usually seen on PowerPC 604 RISC Microprocessor systems. A typical example is a PowerPC 601 RISC Microprocessor system that gets upgraded to a PowerPC 604 RISC Microprocessor system. If performance slows down instead of speeding up, it is most likely due to emulation.

The solution to emulation is to recompile the application in common mode. The default architecture platform for compilations on AIX Version 4 is common architecture. However, the default architecture on AIX Version 3 was for POWER family, POWER2, and PowerPC 601 RISC Microprocessor. If these binaries ran on a PowerPC 604 RISC Microprocessor, some instructions could get emulated.

If binaries need to be compiled on AIX Version 3, then the Full Common Mode APAR must be installed on that AIX Version 3 system, and the application must be compiled with the following options:

```
-qarch=com -qdebug=useabs -bI:/lib/FCM/lowsys.exp
```

Instructions that are not common on all platforms must be removed from code written in assembler, because recompilation is only effective for high-level source code. Routines coded in assembler must be changed so that they do not use missing instructions, because recompilation has no effect in this case.

The first step is to determine if instruction emulation is occurring by using the **emstat** tool (available in AIX 4.2.1 and later).

To determine whether the **emstat** program is installed and available, run the following command:

```
# ls1pp -lI bos.adt.samples
```

This tool resides in the **/usr/samples/kernel** directory.

With operating system versions later than AIX 4.3.3, this command ships with the **perfagent.tools** fileset and has a slightly modified output. To determine whether the **emstat** program is installed and available, run the following command:

```
# ls1pp -lI perfagent.tools
```

The **emstat** command works similarly to the **vmstat** command in that you specify an interval time in seconds, and optionally, the number of intervals. The value in the first column is the cumulative count since system boot, while the value in the second column is the number of instructions emulated during that interval. Emulations on the order of many thousands per second can have an impact on performance.

```
# emstat 1 7
emstat total count      emstat interval count
    21951937             21951937
    21967488             15551
    21974877              7389
    21994354             19477
    22007329             12975
    22018171             10842
    22018171              0
```

Once emulation has been detected, the next step is to determine which application is emulating instructions. This is much harder to determine. One way is to run only one application at a time and monitor it with the **emstat** program. Sometimes certain emulations cause a trace hook to be encountered. This can be viewed in the ASCII trace report file with the words PROGRAM CHECK. The process/thread associated with this trace event is emulating instructions either due to its own code emulating instructions, or it is executing library or code in other modules that are emulating instructions.

Restructuring Executable Programs with the fdpr Program

The **fdpr** (feedback-directed program restructuring) program optimizes executable modules for faster execution and more efficient use of real memory. To determine whether the **fdpr** program is installed and available on your system, run the following command:

```
# ls1pp -lI perfagent.tools
```

The **fdpr** command is a performance-tuning utility that can improve both performance and real memory utilization of user-level application programs. The source code is not necessary as input to the **fdpr** program. However, stripped executable programs are not supported. If source code is available, programs built with the **-qfdpr** compiler flag contain information to assist the **fdpr** program in producing reordered programs with guaranteed functionality. If the **-qfdpr** flag is used, it should be used for all object modules in a program. Static linking will not enhance performance if the **-qfdpr** flag is used.

The **fdpr** tool reorders the instructions in an executable program to improve instruction cache, Translation Lookaside Buffer (TLB), and real memory utilization by doing the following:

- Packing together highly executed code sequences (as determined through profiling)
- Recoding conditional branches to improve hardware branch prediction
- Moving infrequently executed code out of line

For example, given an "if-then-else" statement, the **fdpr** program might conclude that the program uses the else branch more often than the if branch. It will then reverse the condition and the two branches as shown in the following figure.

Figure 18. Example of Conditional Branch Recoding. The illustration shows how conditional branch recoding changes certain code. For example, the code *If (condition) would become If (! condition)*; the code *then stays then*; instructions *becomes other instructions*; *else stays else*; *other instructions become instruction*; and *endif stays endif*.

Large applications (larger than 5 MB) that are CPU-bound can improve execution time up to 23 percent, but typically the performance is improved between 5 and 20 percent. The reduction of real memory requirements for text pages for this type of program can reach 70 percent. The average is between 20 and 50 percent. The numbers depend on the application's behavior and the optimization options issued when using the **fdpr** program.

The **fdpr** processing takes place in three stages:

1. The executable module to be optimized is instrumented to allow detailed performance-data collection.
2. The instrumented executable module is run in a workload provided by the user, and performance data from that run is recorded.
3. The performance data is used to drive a performance-optimization process that results in a restructured executable module that should perform the workload that exercised the instrumented executable program more efficiently. It is critically important that the workload used to drive the **fdpr** program closely match the actual use of the program. The performance of the restructured executable program with workloads that differ substantially from that used to drive the **fdpr** program is unpredictable, but can be worse than that of the original executable program.

As an example, the command:

```
# fdpr -p ProgramName -R3 -x test.sh
```

would use the testcase **test.sh** to run an instrumented form of program **ProgramName**. The output of that run would be used to perform the most aggressive optimization (**-R3**) of the program to form a new module called, by default, **ProgramName.fdpr**. The degree to which the optimized executable program performed better in production than its unoptimized predecessor would depend largely on the degree to which the testcase **test.sh** successfully imitated the production workload.

Note: The **fdpr** program incorporates advanced optimization algorithms that sometimes result in optimized executable programs that do not function in the same way as the original executable module. It is *absolutely essential* that any optimized executable program be thoroughly tested before being used in any production situation; that is, before its output is trusted.

In summary, users of the **fdpr** program should adhere to the following:

- Take pains to use a workload to drive the **fdpr** program that is representative of the intended use.
- Thoroughly test the functioning of the resulting restructured executable program.
- Use the restructured executable program only on the workload for which it has been tuned.

Controlling Contention for the CPU

AIX Version 4 introduced the use of threads to control processor time consumption, but most of the system management tools still refer to the process in which a thread is running, rather than the thread itself.

Controlling the Priority of User Processes

User-process priorities can be manipulated using the **nice** or **renice** command or the **setpri()** subroutine, and displayed with the **ps** command. An overview of priority is provided in Process and Thread Priority.

Priority calculation is employed to accomplish the following:

- Share the CPU among threads
- Prevent starvation of any thread
- Penalize compute-bound threads
- Increase continuous discrimination between threads over time

The degree to which the user priorities can be manipulated is release-dependent. The algorithm for calculating priority value in AIX 4.3.1 and prior releases is more limiting than the current algorithm. The algorithm was changed in AIX 4.3.2 so that user priorities can be manipulated more than in previous releases. There is improved distinction between foreground and background processes. Using a given nice value will have a greater effect on CPU utilization. See “Priority Calculation” on page 118.

Running a Command with the nice Command

Any user can run a command at a less-favorable-than-normal priority by using the **nice** command. Only the root user can use the **nice** command to run commands at a more-favorable-than-normal priority. In this case, the **nice** command values range between -20 and 19.

With the **nice** command, the user specifies a value to be added to or subtracted from the standard nice value. The modified nice value is used for the process that runs the specified command. The priority of the process is still non-fixed; that is, the priority value is still recalculated periodically based on the CPU usage, nice value, and minimum user-process-priority value.

The standard nice value of a foreground process is 20 (24 for a ksh background process). The following command would cause the **vmstat** command to be run in the foreground with a nice value of 25 (instead of the standard 20), resulting in a less favorable priority.

```
# nice -n 5 vmstat 10 3 > vmstat.out
```

If you use the root login, the **vmstat** command can be run at a more favorable priority with the following:

```
# nice -n -5 vmstat 10 3 > vmstat.out
```

If you were not using root login and issued the preceding example **nice** command, the **vmstat** command would still be run but at the standard nice value of 20, and the **nice** command would not issue any error message.

Setting a Fixed Priority with the setpri Subroutine

An application that runs under the root user ID can use the **setpri()** subroutine to set its own priority or that of another process. For example:

```
retcode = setpri(0,59);
```

would give the current process a fixed priority of 59. If the **setpri()** subroutine fails, it returns -1.

The following program accepts a priority value and a list of process IDs and sets the priority of all of the processes to the specified value.

```
/*
  fixprocpri.c
  Usage: fixprocpri priority PID . . .
*/

#include <sys/sched.h>
#include <stdio.h>
#include <sys/errno.h>
```

```

main(int argc, char **argv)
{
    pid_t ProcessID;
    int Priority, ReturnP;

    if( argc < 3 ) {
        printf(" usage - setpri priority pid(s) \n");
        exit(1);
    }

    argv++;
    Priority=atoi(*argv++);
    if ( Priority < 50 ) {
        printf(" Priority must be >= 50 \n");
        exit(1);
    }

    while (*argv) {
        ProcessID=atoi(*argv++);
        ReturnP = setpri(ProcessID, Priority);
        if ( ReturnP > 0 )
            printf("pid=%d new pri=%d old pri=%d\n",
                (int)ProcessID, Priority, ReturnP);
        else {
            perror(" setpri failed ");
            exit(1);
        }
    }
}

```

Displaying Process Priority with the ps Command

The **-l** (lowercase L) flag of the **ps** command displays the nice values and current priority values of the specified processes. For example, you can display the priorities of all of the processes owned by a given user with the following:

```

# ps -lu hoetzel
  F S UID  PID PPID  C PRI NI ADDR  SZ  WCHAN  TTY  TIME CMD
241801 S 200 7032 7286  0 60 20 1b4c  108
200801 S 200 7568 7032  0 70 25 2310  88 5910a58 pts/2 0:00 vmstat
241801 S 200 8544 6494  0 60 20 154b  108
                pts/0 0:00 ksh

```

The output shows the result of the **nice -n 5** command described previously. Process 7568 has an inferior priority of 70. (The **ps** command was run by a separate session in superuser mode, hence the presence of two TTYs.)

If one of the processes had used the **setpri(10758, 59)** subroutine to give itself a fixed priority, a sample **ps -l** output would be as follows:

```

  F S UID  PID PPID  C PRI NI ADDR  SZ  WCHAN  TTY  TIME CMD
200903 S  0 10758 10500  0 59 -- 3438  40 4f91f98 pts/0 0:00 fixpri

```

Modifying the Priority with the renice Command

The **renice** command alters the nice value, and thus the priority, of one or more processes that are already running. The processes are identified either by process ID, process group ID, or the name of the user who owns the processes.

For AIX Version 4, the syntax of the **renice** command has been changed to complement the alternative syntax of the **nice** command, which uses the **-n** flag to identify the nice-value increment.

The **renice** command cannot be used on fixed-priority processes. A non-root user can specify a value to be added to, but not subtracted from the nice value of one or more running processes. The modification is

done to the nice values of the processes. The priority of these processes is still non-fixed. Only the root user can use the **renice** command to alter the priority value within the range of -20 to 20, or subtract from the nice value of one or more running processes.

To continue the example, use the **renice** command to alter the nice value of the **vmstat** process that you started with **nice**.

```
# renice -n -5 7568
# ps -lu hoetzel
  F S UID  PID PPID  C PRI NI ADDR  SZ  WCHAN  TTY  TIME CMD
241801 S 200 7032 7286  0  60 20 1b4c 108          pts/2  0:00 ksh
200801 S 200 7568 7032  0  60 20 2310  92 5910a58 pts/2  0:00 vmstat
241801 S 200 8544 6494  0  60 20 154b 108          pts/0  0:00 ksh
```

Now the process is running at a more favorable priority that is equal to the other foreground processes. To undo the effects of this, you could issue the following:

```
# renice -n 5 7569
# ps -lu hoetzel
  F S UID  PID PPID  C PRI NI ADDR  SZ  WCHAN  TTY  TIME CMD
241801 S 200 7032 7286  0  60 20 1b4c 108          pts/2  0:00 ksh
200801 S 200 7568 7032  1  70 25 2310  92 5910a58 pts/2  0:00 vmstat
241801 S 200 8544 6494  0  60 20 154b 108          pts/0  0:00 ksh
```

In these examples, the **renice** command was run by the root user. When run by an ordinary user ID, there are two major limitations to the use of the **renice** command:

- Only processes owned by that user ID can be specified.
- The nice value of the process cannot be decreased, not even to return the process to the default priority after making its priority less favorable with the **renice** command.

Clarification of the nice and renice Command Syntax

The **nice** and **renice** commands have different ways of specifying the amount that is to be added to the standard nice value of 20.

For AIX Version 4, the syntax of the **renice** command has been changed to complement the alternative syntax of the **nice** command, which uses the **-n** flag to identify the nice-value increment.

Command	Command	Resulting nice Value	Best Priority Value in AIX 4.3.1	Best Priority Value in AIX 4.3.2 and Subsequent Releases
nice -n 5	renice -n 5	25	65	70
nice -n +5	renice -n +5	25	65	70
nice -n -5	renice -n -5	15	55	55

Tuning the Thread-Priority-Value Calculation

This section discusses tuning using the following:

- Priority Calculation
- The **schedtune** command

The **schedtune** command and several enhancements to the CPU scheduler permit changes to the parameters used to calculate the priority value for each thread. See Process and Thread Priority for background information on priority.

To determine whether the **schedtune** program is installed and available, run the following command:

```
# ls|pp -lI bos.adt.samples
```

Priority Calculation

The formula for calculating the priority value is:

$$\text{priority value} = \text{base priority} + \text{nice penalty} + (\text{CPU penalty based on recent CPU usage})$$

The recent CPU usage value of a given thread is incremented by 1 each time that thread is in control of the CPU when the timer interrupt occurs (every 10 milliseconds). The recent CPU usage value is displayed as the C column in the **ps** command output. The maximum value of recent CPU usage is 120.

The default algorithm calculates the CPU penalty by dividing recent CPU usage by 2. The CPU-penalty-to-recent-CPU-usage ratio is therefore 0.5. This ratio is controlled by a value called *R* (the default is 16). The formula is as follows:

$$\text{CPU_penalty} = C * R/32$$

Once a second, the default algorithm divides the recent CPU usage value of every thread by 2. The recent-CPU-usage-decay factor is therefore 0.5. This factor is controlled by a value called *D* (the default is 16). The formula is as follows:

$$C = C * D/32$$

For some users, the algorithm in AIX 4.3.1 does not allow enough distinction between foreground and background processes. The algorithm for calculating priority value was changed in AIX 4.3.2 to increase the impact on priorities when the nice value is changed. As the units of CPU time increase, the priority decreases with the nice effect. Using `schedtune -r -d` can give additional control over the priority calculation by setting new values for *R* and *D*. See “Tuning with the schedtune Command” for further information.

The algorithm guarantees that threads whose nice values are the default of 20 will behave exactly as they did in AIX 4.3.1 and prior releases. When the nice value is not equal to the default, the priority will be affected more due to the use of two formulas.

Begin with the following equation:

$$p_nice = \text{base priority} + \text{nice value}$$

Now use the following formula:

```
If p_nice > 60,  
    then x_nice = (p_nice * 2) - 60,  
    else x_nice = p_nice.
```

If the nice value is greater than 20, then it has double the impact on the priority value than if it was less than or equal to 20. The new priority calculation (ignoring integer truncation) is as follows:

$$\text{priority value} = x_nice + [(x_nice + 4)/64 * C*(R/32)]$$

Note: If the nice value is the default, the formulas for AIX 4.3.1 and AIX 4.3.2 yield the same results.

Tuning with the schedtune Command

Tuning is accomplished through two options of the **schedtune** command: **-r** and **-d**. Each option specifies a parameter that is an integer from 0 through 32. The parameters are applied by multiplying by the parameter's value and then dividing by 32. The default *r* and *d* values are 16, which yields the same behavior as the original algorithm [(*D*=*R*=16)/32=0.5]. The new range of values permits a far wider spectrum of behaviors. For example:

```
# /usr/samples/kernel/schedtune -r 0
```

[(*R*=0)/32=0, (*D*=16)/32=0.5] would mean that the CPU penalty was always 0, making priority a function of the nice value only. No background process would get any CPU time unless there were no dispatchable foreground processes at all. The priority values of the threads would effectively be constant, although they would not technically be fixed-priority threads.

```
# /usr/samples/kernel/schedtune -r 5
```

[(R=5)/32=0.15625, (D=16)/32=0.5] would mean that a foreground process would never have to compete with a background process started with the command **nice -n 10**. The limit of 120 CPU time slices accumulated would mean that the maximum CPU penalty for the foreground process would be 18.

```
# /usr/samples/kernel/schedtune -r 6 -d 16
```

[(R=6)/32=0.1875, (D=16)/32=0.5] would mean that, if the background process were started with the command **nice -n 10**, it would be at least one second before the background process began to receive any CPU time. Foreground processes, however, would still be distinguishable on the basis of CPU usage. Long-running foreground processes that should probably be in the background would ultimately accumulate enough CPU usage to keep them from interfering with the true foreground.

```
# /usr/samples/kernel/schedtune -r 32 -d 32
```

[(R=32)/32=1, (D=32)/32=1] would mean that long-running threads would reach a C value of 120 and remain there, contending on the basis of their **nice** values. New threads would have priority, regardless of their **nice** value, until they had accumulated enough time slices to bring them within the priority value range of the existing threads.

Here are some guidelines for R and D:

- Smaller values of R narrow the priority range and make the **nice** value have more of an impact on the priority.
- Larger values of R widen the priority range and make the **nice** value have less of an impact on the priority.
- Smaller values of D decay CPU usage at a faster rate and can cause CPU-intensive threads to be scheduled sooner.
- Larger values of D decay CPU usage at a slower rate and penalize CPU-intensive threads more (thus favoring interactive-type threads).

If you conclude that one or both parameters need to be modified to accommodate your workload, you can enter the **schedtune** command while logged on as root user. The changed values will remain until the next **schedtune** command modifies them or until the next system boot. Values can be reset to their defaults with the command **schedtune -D**, but remember that all **schedtune** parameters are reset by that command, including VMM memory load control parameters. To make a change to the parameters that will persist across boots, add an appropriate line at the end of the **/etc/inittab** file.

Example of a Priority Calculation

The example shows R=4 and D=31 and assumes no other runnable threads:

```
current_effective_priority
|
| base process priority
|   | nice value
|   | count (time slices consumed)
|   | (schedtune -r)
|   |
time 0      p = 40 + 20 + (0 * 4/32) = 60
time 10 ms  p = 40 + 20 + (1 * 4/32) = 60
time 20 ms  p = 40 + 20 + (2 * 4/32) = 60
time 30 ms  p = 40 + 20 + (3 * 4/32) = 60
time 40 ms  p = 40 + 20 + (4 * 4/32) = 60
time 50 ms  p = 40 + 20 + (5 * 4/32) = 60
time 60 ms  p = 40 + 20 + (6 * 4/32) = 60
time 70 ms  p = 40 + 20 + (7 * 4/32) = 60
time 80 ms  p = 40 + 20 + (8 * 4/32) = 61
time 90 ms  p = 40 + 20 + (9 * 4/32) = 61
time 100ms  p = 40 + 20 + (10 * 4/32) = 61
.
(skipping forward to 1000msec or 1 second)
.
```

```

time 1000ms    p = 40 + 20 + (100 * 4/32) = 72
time 1000ms    swapper recalculates the accumulated CPU usage counts of
                all processes. For the above process:
                new_CPU_usage = 100 * 31/32 = 96 (if d=31)
                after decaying by the swapper: p = 40 + 20 + ( 96 * 4/32) = 72
                (if d=16, then p = 40 + 20 + (100/2 * 4/32) = 66)
time 1010ms    p = 40 + 20 + ( 97 * 4/32) = 72
time 1020ms    p = 40 + 20 + ( 98 * 4/32) = 72
time 1030ms    p = 40 + 20 + ( 99 * 4/32) = 72
                ..
time 1230ms    p = 40 + 20 + (119 * 4/32) = 74
time 1240ms    p = 40 + 20 + (120 * 4/32) = 75    count <= 120
time 1250ms    p = 40 + 20 + (120 * 4/32) = 75
time 1260ms    p = 40 + 20 + (120 * 4/32) = 75
                ..
time 2000ms    p = 40 + 20 + (120 * 4/32) = 75
time 2000ms    swapper recalculates the counts of all processes. For above
time 2010ms    p = 40 + 20 + (117 * 4/32) = 74

```

Modifying the Scheduler Time Slice with the `schedtune` Command

The length of the scheduler time slice can be modified with the `schedtune` command. To change the time slice, use the `schedtune -t` option.

In AIX Version 4, the value of `-t` is the number of ticks for the time slice and only `SCHED_RR` threads will use the nondefault time slice value (see *Scheduling Policy for Threads* for a description of fixed priority threads).

Changing the time slice takes effect instantly and does not require a reboot.

A thread running with `SCHED_OTHER` or `SCHED_RR` scheduling policy can use the CPU for up to a full time slice (the default time slice being 1 clock tick), a clock tick being 10 ms.

In some situations, too much context switching is occurring and the overhead of dispatching threads can be more costly than allowing these threads to run for a longer time slice. In these cases, increasing the time slice might have a positive impact on the performance of fixed-priority threads. Use the `vmstat` and `sar` commands for determining the number of context switches per second.

In an environment in which the length of the time slice has been increased, some applications might not need or should not have the full time slice. These applications can give up the processor explicitly with the `yield()` system call (as can programs in an unmodified environment). After a `yield()` call, the calling thread is moved to the end of the dispatch queue for its priority level.

CPU-Efficient User ID Administration (The `mkpasswd` Command)

To improve login response time and conserve CPU time in systems with many users, the operating system can use a hashed version of the `/etc/passwd` file to look up user IDs. When this facility is used, the `/etc/passwd` file still exists, but is not used in normal processing. The hashed versions of the file are built by the `mkpasswd` command. If the hashed versions are not current, login processing reverts to a slow, CPU-intensive sequential search through `/etc/passwd`.

Prior to AIX 4.3, the command to run is `mkpasswd /etc/passwd`. This command creates a `/etc/passwd.pag` and `/etc/passwd.dir` file, and lookups of `/etc/passwd` will do a hashed lookup into `passwd.pag` (as long as this file is newer than `/etc/passwd` and `/etc/security/passwd`. Otherwise, lookups will fall back to the default behavior).

Starting with AIX 4.3, the command to run is `mkpasswd -f`. This command creates indexed versions of `/etc/passwd`, `/etc/security/passwd`, and `/etc/security/lastlog`. The files created are `/etc/passwd.nm.idx`,

/etc/passwd.id.idx, **/etc/security/passwd.idx**, and **/etc/security/lastlog.idx**. Note that this will greatly enhance performance of applications that also need the encrypted password (such as login and any other program that needs to do password authentication).

Applications can also be changed to use alternative routines such as **__getpwent()** instead of **getpwent()**, **__getpwnam_shadow(name,0)** instead of **getpwnam(name)**, or **__getpwuid_shadow(uid,0)** instead of **getpwuid(uid)** to do name/ID resolution in cases where the encrypted password is not needed. This prevents a lookup of **/etc/security/passwd**.

Do not edit the password files by hand because the time stamps of the database files (**.pag** or **.idx**) will not be in sync and the default lookup method (linear) will be used. If the **passwd**, **mkuser**, **chuser**, **rmuser** commands (or the SMIT command equivalents, with fast paths of the same name) are used to administer user IDs, the hashed files are kept up to date automatically. If the **/etc/passwd** file is changed with an editor or with the **pwdadm** command, the hashed or index files must be rebuilt.

Note: The **mkpasswd** command does not affect NIS, DCE, or LDAP user databases.

Chapter 7. Monitoring and Tuning Memory Use

The memory of a system is almost constantly filled to capacity. Even if currently running programs do not consume all available memory, the operating system retains in memory the text pages of programs that ran earlier and the files that they used. There is no cost associated with this retention, because the memory would have been unused anyway. In many cases, the programs or files will be used again, which reduces disk I/O.

This chapter describes how memory use can be measured and modified. It contains the following major sections:

- Determining How Much Memory Is Being Used
- Finding Memory-Leaking Programs
- Assessing Memory Requirements Through the `rmss` Command
- Tuning VMM Memory Load Control with the `schedtune` Command
- Tuning VMM Page Replacement with the `vmtune` Command
- Tuning Paging-Space Thresholds
- Choosing a Page Space Allocation Method
- Using Shared Memory

Readers who are not familiar with the operating system's virtual-memory management may want to look at Performance Overview of the Virtual Memory Manager (VMM) before continuing.

Determining How Much Memory Is Being Used

Several performance tools provide reports of memory usage. The reports of most interest are from the `vmstat`, `ps`, and `svmon` commands.

The `vmstat` Command (Memory)

The `vmstat` command summarizes the total *active* virtual memory used by all of the processes in the system, as well as the number of real-memory page frames on the free list. Active virtual memory is defined as the number of virtual-memory working segment pages that have actually been touched (for a definition see Late Page Space Allocation). This number can be larger than the number of real page frames in the machine, because some of the active virtual-memory pages may have been written out to paging space.

When determining if a system might be short on memory or if some memory tuning needs to be done, run the `vmstat` command over a set interval and examine the `pi` and `po` columns on the resulting report. These columns indicate the number of paging space page-ins per second and the number of paging space page-outs per second. If the values are constantly non-zero, there might be a memory bottleneck. Having occasional non-zero values is not be a concern because paging is the main principle of virtual memory.

```
# vmstat 2 10
kthr      memory          page          faults          cpu
-----
 r  b   avm    fre re  pi  po  fr  sr  cy  in  sy  cs  us  sy  id  wa
1  3 113726  124  0  14   6 151  600  0 521 5533 816 23 13  7  57
0  3 113643  346  0   2  14 208  690  0 585 2201 866 16  9  2  73
0  3 113659  135  0   2   2 108  323  0 516 1563 797 25  7  2  66
0  2 113661  122  0   3   2 120  375  0 527 1622 871 13  7  2  79
0  3 113662  128  0  10   3 134  432  0 644 1434 948 22  7  4  67
1  5 113858  238  0  35   1 146  422  0 599 5103 903 40 16  0  44
0  3 113969  127  0   5  10 153  529  0 565 2006 823 19  8  3  70
0  3 113983  125  0  33   5 153  424  0 559 2165 921 25  8  4  63
0  3 113682  121  0  20   9 154  470  0 608 1569 1007 15  8  0  77
0  4 113701  124  0   3  29 228  635  0 674 1730 1086 18  9  0  73
```

Notice the high I/O wait in the output and also the number of threads on the blocked queue. Most likely, the I/O wait is due to the paging in/out from paging space.

To see if the system has performance problems with its VMM, examine the columns under memory and page:

- **memory**

Provides information about the real and virtual memory.

- **avm**

The **avm** (Active Virtual Memory) column gives the average number of 4 K pages that are allocated to paging space. The **avm** value can be used to calculate the amount of paging space assigned to executing processes.

Note: Starting with AIX 4.3.2, there is a slight change in reporting this value. See Looking at Paging Space and Virtual Memory for an explanation.

The number in the **avm** field divided by 256 will yield the approximate number of megabytes (MB) allocated to paging space systemwide. Prior to AIX 4.3.2 the same information is reflected in the Percent Used column of the **lsps -s** command output or with the **svmon -G** command under the **pg space inuse** field.

- **fre**

The **fre** column shows the average number of free memory pages. A page is a 4 KB area of real memory. The system maintains a buffer of memory pages, called the free list, that will be readily accessible when the VMM needs space. The minimum number of pages that the VMM keeps on the free list is determined by the **minfree** parameter of the **vmtune** command (for details, see Tuning VMM Page Replacement with the **vmtune** Command).

When an application terminates, all of its working pages are immediately returned to the free list. Its persistent pages (files), however, remain in RAM and are not added back to the free list until they are stolen by the VMM for other programs. Persistent pages are also freed if the corresponding file is deleted.

For this reason, the **fre** value may not indicate all the real memory that can be readily available for use by processes. If a page frame is needed, then persistent pages related to terminated applications are among the first to be handed over to another program.

If the **fre** value is substantially above the **maxfree** value, it is unlikely that the system is *thrashing*. Thrashing means that the system is continuously paging in and out. However, if the system is experiencing thrashing, you can be assured that the **fre** value will be small.

- **page**

Information about page faults and paging activity. These are averaged over the interval and given in units per second.

- **re**

Note: In AIX Version 4, reclaiming is no longer supported because the value it delivered by providing limited information about the performance of the system was outweighed by the negative affect on system performance due to the algorithm that kept track of reclaims.

- **pi**

The **pi** column details the number (rate) of pages paged in from paging space. Paging space is the part of virtual memory that resides on disk. It is used as an overflow when memory is over committed. Paging space consists of logical volumes dedicated to the storage of working set pages that have been stolen from real memory. When a stolen page is referenced by the process, a page fault occurs, and the page must be read into memory from paging space.

Due to the variety of configurations of hardware, software and applications, there is no absolute number to look out for. But five page-ins per second per paging space should be the upper limit. This guideline should not be rigidly adhered to, but used as a reference. This field is important as a key

indicator of paging-space activity. If a page-in occurs, there must have been a previous page-out for that page. It is also likely in a memory-constrained environment that each page-in will force a different page to be stolen and, therefore, paged out. But systems could also work fine when they have close to 10 pi per second for 1 minute and then work without any page-ins.

– **po**

The po column shows the number (rate) of pages paged out to paging space. Whenever a page of working storage is stolen, it is written to paging space, if it does not yet reside in paging space or if it was modified. If not referenced again, it will remain on the paging device until the process terminates or disclaims the space. Subsequent references to addresses contained within the faulted-out pages results in page faults, and the pages are paged in individually by the system. When a process terminates normally, any paging space allocated to that process is freed. If the system is reading in a significant number of persistent pages (files), you might see an increase in po without corresponding increases in pi. This does not necessarily indicate thrashing, but may warrant investigation into data-access patterns of the applications.

– **fr**

Number of pages that were freed per second by the page-replacement algorithm during the interval. As the VMM page-replacement routine scans the Page Frame Table (PFT), it uses criteria to select which pages are to be stolen to replenish the free list of available memory frames. The criteria include both kinds of pages, working (computational) and file (persistent) pages. Just because a page has been freed, it does not mean that any I/O has taken place. For example, if a persistent storage (file) page has not been modified, it will not be written back to the disk. If I/O is not necessary, minimal system resources are required to free a page.

– **sr**

Number of pages that were examined per second by the page-replacement algorithm during the interval. The VMM page-replacement code scans the PFT and steals pages until the number of frames on the free list is at least the **maxfree** value. The page-replacement code might have to scan many entries in the PFT before it can steal enough to satisfy the free list requirements. With stable, unfragmented memory, the scan rate and free rate might be nearly equal. On systems with multiple processes using many different pages, the pages are more volatile and disjoint. In this scenario, the scan rate might greatly exceed the free rate.

Memory is over committed when the ratio of fr to sr (fr:sr) is high.

An fr:sr ratio of 1:4 means that for every page freed, four pages had to be examined. It is difficult to determine a memory constraint based on this ratio alone, and what constitutes a high ratio is workload/application dependent.

– **cy**

Number of cycles per second of the clock algorithm. The VMM uses a technique known as the clock algorithm to select pages to be replaced. This technique takes advantage of a referenced bit for each page as an indication of what pages have been recently used (referenced). When the page-stealer routine is called, it cycles through the PFT, examining each page's referenced bit.

The cy column shows how many times per second the page-replacement code has scanned the PFT. Because the free list can be replenished without a complete scan of the PFT and because all of the **vmstat** fields are reported as integers, this field is usually zero. If not, it indicates a complete scan of the PFT, and the stealer has to scan the PFT again, because fre is still under the **maxfree** value.

One way to determine the appropriate amount of RAM for a system is to look at the largest value for avm as reported by the **vmstat** command. Multiply that by 4 K to get the number of bytes and then compare that to the number of bytes of RAM on the system. Ideally, avm should be smaller than total RAM. If not, some amount of virtual memory paging will occur. How much paging occurs will depend on the difference between the two values. Remember, the idea of virtual memory is that it gives us the capability of addressing more memory than we have (some of the memory is in RAM and the rest is in paging space). But if there is far more virtual memory than real memory, this could cause excessive paging which then results in delays. If avm is lower than RAM, then paging-space paging could be caused by RAM being filled

up with file pages. In that case, tuning the **minperm/maxperm** values, could reduce the amount of paging-space paging (see Tuning VMM Page Replacement with the vmtune Command).

The **vmstat -I** Command

In operating system versions later than AIX 4.3.3, the **vmstat -I** (uppercase i) command displays additional information, such as file pages in per-second, file pages out per-second (that is, any VMM page-ins and page-outs that are not paging space page-ins or paging space page-outs). The **re** and **cy** columns are not reported with this flag.

The **vmstat -s** Command

The summary (**-s**) option sends a summary report to standard output starting from system initialization expressed in absolute counts rather than on an interval basis. The recommended way of using these statistics is to run this command before a workload, save the output, and then run it again after the workload and save its output. The next step is to determine the difference between the two sets of output. An **awk** script called **vmstatit** that does this automatically is provided in Determining Whether the Problem is Related to Disk or Memory.

```
# vmstat -s
3231543 total address trans. faults
 63623 page ins
383540 page outs
  149 paging space page ins
  832 paging space page outs
   0 total reclaims
807729 zero filled pages faults
 4450 executable filled pages faults
429258 pages examined by clock
   8 revolutions of the clock hand
175846 pages freed by the clock
 18975 backtracks
   0 lock misses
   40 free frame waits
   0 extend XPT waits
 16984 pending I/O waits
186443 start I/Os
186443 iodones
141695229 cpu context switches
317690215 device interrupts
   0 software interrupts
   0 traps
55102397 syscalls
```

The page-in and page-out numbers in the summary represent virtual memory activity to page in or out pages from page space and file space. The paging space ins and outs are representative of only page space. If you are experiencing considerable I/O wait time, but are not memory-constrained, the problem might be due to poor distribution of I/O across drives. To determine if the problem is due to paging space or files, take multiple samples of the **vmstat -s** command and see if the page ins and outs to paging space are the majority of the total paging. If the system is paging too much, using the **vmtune** command might help (see Tuning VMM Page Replacement with the vmtune Command). Creating separate paging spaces on separate volumes might provide some benefit, but increasing the memory would definitely help.

The **ps** Command

The **ps** command can also be used to monitor memory usage of individual processes. The **ps v PID** command provides the most comprehensive report on memory-related statistics for an individual process, such as:

- Page faults
- Size of working segment that has been touched
- Size of working segment and code segment in memory
- Size of text segment

- Size of resident set
- Percentage of real memory used by this process

An example:

```
# ps v
  PID  TTY STAT  TIME PGIN  SIZE  RSS  LIM  TSIZ  TRS %CPU %MEM COMMAND
36626 pts/3 A    0:00   0   316  408 32768  51   60  0.0  0.0 ps v
```

The most important columns on the resulting **ps** report are described as follows:

- PGIN** Number of page-ins caused by page faults. Since all I/O is classified as page faults, this is basically a measure of I/O volume.
- SIZE** Virtual size (in paging space) in kilobytes of the data section of the process (displayed as SZ by other flags). This number is equal to the number of working segment pages of the process that have been touched times 4. If some working segment pages are currently paged out, this number is larger than the amount of real memory being used. SIZE includes pages in the private segment and the shared-library data segment of the process.
- RSS** Real-memory (resident set) size in kilobytes of the process. This number is equal to the sum of the number of working segment and code segment pages in memory times 4. Remember that code segment pages are shared among all of the currently running instances of the program. If 26 **ksh** processes are running, only one copy of any given page of the **ksh** executable program would be in memory, but the **ps** command would report that code segment size as part of the RSS of each instance of the **ksh** program.
- TSIZ** Size of text (shared-program) image. This is the size of the text section of the executable file. Pages of the text section of the executable program are only brought into memory when they are touched, that is, branched to or loaded from. This number represents only an upper bound on the amount of text that could be loaded. The TSIZ value does not reflect actual memory usage. This TSIZ value can also be seen by executing the **dump -ov** command against an executable program (for example, **dump -ov /usr/bin/ls**).
- TRS** Size of the resident set (real memory) of text. This is the number of code segment pages times 4. This number exaggerates memory use for programs of which multiple instances are running. The TRS value can be higher than the TSIZ value because other pages may be included in the code segment such as the XCOFF header and the loader section.

%MEM

Calculated as the sum of the number of working segment and code segment pages in memory times 4 (that is, the RSS value), divided by the size of the real memory of the machine in KB, times 100, rounded to the nearest full percentage point. This value attempts to convey the percentage of real memory being used by the process. Unfortunately, like RSS, it tends to exaggerate the cost of a process that is sharing program text with other processes. Further, the rounding to the nearest percentage point causes all of the processes in the system that have RSS values under 0.005 times real memory size to have a %MEM of 0.0.

Note: The **ps** command does not indicate memory consumed by shared memory segments or memory-mapped segments. Because many applications use shared memory or memory-mapped segments, the **svmon** command is a better tool to view the memory usage of these segments.

The svmon Command

The **svmon** command provides a more in-depth analysis of memory usage. It is more informative, but also more intrusive, than the **vmstat** and **ps** commands. The **svmon** command captures a snapshot of the current state of memory. However, it is not a true snapshot because it runs at the user level with interrupts enabled.

To determine whether **svmon** is installed and available, run the following command:

```
# ls1pp -lI perfagent.tools
```

The **svmon** command can only be executed by the root user.

If an interval is used (-i option), statistics will be displayed until the command is killed or until the number of intervals, which can be specified right after the interval, is reached.

You can use four different reports to analyze the displayed information:

Global (-G)

Displays statistics describing the real memory and paging space in use for the whole system.

Process (-P)

Displays memory usage statistics for active processes.

Segment (-S)

Displays memory usage for a specified number of segments or the top ten highest memory-usage processes in descending order.

Detailed Segment (-D)

Displays detailed information on specified segments.

Additional reports are available in AIX 4.3.3 and later, as follows:

User (-U)

Displays memory usage statistics for the specified login names. If no list of login names is supplied, memory usage statistics display all defined login names.

Command (-C)

Displays memory usage statistics for the processes specified by command name.

Workload Management Class (-W)

Displays memory usage statistics for the specified workload management classes. If no classes are supplied, memory usage statistics display all defined classes.

To support 64-bit applications, the output format of the **svmon** command was modified in AIX 4.3.3 and later.

Additional reports are available in operating system versions later than 4.3.3, as follows:

Frame (-F)

Displays information about frames. When no frame number is specified, the percentage of used memory is reported. When a frame number is specified, information about that frame is reported.

Tier (-T)

Displays information about tiers, such as the tier number, the superclass name when the **-a** flag is used, and the total number of pages in real memory from segments belonging to the tier.

How Much Memory is in Use

To print out global statistics, use the **-G** flag. In this example, we will repeat it five times at two-second intervals.

```
# svmon -G -i 2 5
  m e m o r y           i n u s e           p i n           p g s p a c e
  size inuse free  pin  work pers clnt  work  pers  clnt  size  inuse
16384 16250  134 2006 10675 2939 2636 2006   0   0  40960 12674
16384 16254  130 2006 10679 2939 2636 2006   0   0  40960 12676
16384 16254  130 2006 10679 2939 2636 2006   0   0  40960 12676
16384 16254  130 2006 10679 2939 2636 2006   0   0  40960 12676
16384 16254  130 2006 10679 2939 2636 2006   0   0  40960 12676
```

The columns on the resulting **svmon** report are described as follows:

memory

Statistics describing the use of real memory, shown in 4 K pages.

size Total size of memory in 4 K pages.

inuse Number of pages in RAM that are in use by a process plus the number of persistent pages that belonged to a terminated process and are still resident in RAM. This value is the total size of memory minus the number of pages on the free list.

free Number of pages on the free list.

pin Number of pages pinned in RAM (a pinned page is a page that is always resident in RAM and cannot be paged out).

in use Detailed statistics on the subset of real memory in use, shown in 4 K frames.

work Number of working pages in RAM.

pers Number of persistent pages in RAM.

clnt Number of client pages in RAM (client page is a remote file page).

pin Detailed statistics on the subset of real memory containing pinned pages, shown in 4 K frames.

work Number of working pages pinned in RAM.

pers Number of persistent pages pinned in RAM.

clnt Number of client pages pinned in RAM.

pg space

Statistics describing the use of paging space, shown in 4 K pages. This data is reported only if the **-r** flag is not used. The value reported starting with AIX 4.3.2 is the actual number of paging-space pages used (which indicates that these pages were paged out to the paging space). This differs from the **vmstat** command in that **vmstat**'s **avm** column which shows the virtual memory accessed but not necessarily paged out.

size Total size of paging space in 4 K pages.

inuse Total number of allocated pages.

In our example, there are 16384 pages of total size of memory. Multiply this number by 4096 to see the total real memory size (64 MB). While 16250 pages are in use, there are 134 pages on the free list and 2006 pages are pinned in RAM. Of the total pages in use, there are 10675 working pages in RAM, 2939 persistent pages in RAM, and 2636 client pages in RAM. The sum of these three parts is equal to the **inuse** column of the memory part. The **pin** part divides the pinned memory size into working, persistent and client categories. The sum of them is equal to the **pin** column of the memory part. There are 40960 pages (160 MB) of total paging space, and 12676 pages are in use. The **inuse** column of memory is usually greater than the **inuse** column of pg space because memory for file pages is not freed when a program completes, while paging-space allocation is.

In AIX 4.3.3 and later, systems the output of the same command looks similar to the following:

```
# svmon -G -i 2 5
```

	size	inuse	free	pin	virtual
memory	65527	64087	1440	5909	81136
pg space	131072	55824			

```

pin          work      pers      cInt
in use      5918      0         0
47554      13838     2695

memory      size      inuse     free      pin      virtual
pg space    65527    64091    1436     5909     81137
131072     55824

pin          work      pers      cInt
in use      5918      0         0
47558      13838     2695

memory      size      inuse     free      pin      virtual
pg space    65527    64091    1436     5909     81137
131072     55824

pin          work      pers      cInt
in use      5918      0         0
47558      13838     2695

47636      13837     2695

```

The additional output field is the `virtual` field, which shows the number of pages allocated in the system virtual space.

Who is Using Memory?

The following command displays the memory usage statistics for the top ten processes. If you do not specify a number, it will display all the processes currently running in this system.

```
# svmon -Pau 10
```

Pid	Command	Inuse	Pin	Pgspace

...

```

The output is divided into summary and detail sections. The summary section lists the top ten highest memory-usage processes in descending order.

Pid 15012 is the process ID that has the highest memory usage. The Command indicates the command name, in this case `maker4X.exe`. The Inuse column (total number of pages in real memory from segments that are used by the process) shows 4783 pages (each page is 4 KB). The Pin column (total number of pages pinned from segments that are used by the process) shows 1174 pages. The Pgspace column (total number of paging-space pages that are used by the process) shows 4781 pages.

The detailed section displays information about each segment for each process that is shown in the summary section. This includes the segment ID, the type of the segment, description (a textual description of the segment, including the volume name and i-node of the file for persistent segments), number of pages in RAM, number of pinned pages in RAM, number of pages in paging space, and address range.

The Address Range specifies one range for a persistent or client segment and two ranges for a working segment. The range for a persistent or a client segment takes the form '0..x,' where x is the maximum number of virtual pages that have been used. The range field for a working segment can be '0..x : y.65535', where 0..x contains global data and grows upward, and y.65535 contains stack area and grows downward. For the address range, in a working segment, space is allocated starting from both ends and working towards the middle. If the working segment is non-private (kernel or shared library), space is allocated differently. In this example, the segment ID 1b9d is a private working segment; its address range is 0..1306 : 65307..65535. The segment ID 909 is a shared library text working segment; its address range is 0..65535.

A segment can be used by multiple processes. Each page in real memory from such a segment is accounted for in the Inuse field for each process using that segment. Thus, the total for Inuse may exceed the total number of pages in real memory. The same is true for the Pgspace and Pin fields. The sum of Inuse, Pin, and Pgspace of all segments of a process is equal to the numbers in the summary section.

You can use one of the following commands to display the file name associated with the i-node:

- **ncheck -i** *i-node_number volume_name*
- **find file_system_associated_with_lv_name -xdev -inum inode_number -print**

To get a similar output in AIX 4.3.3 and later, use the following command:

```
# svmon -Put 10
```

```

```

...

The Vsid column is the virtual segment ID, and the Esid column is the effective segment ID. The effective segment ID reflects the segment register that is used to access the corresponding pages.

Detailed Information on a Specific Segment ID

The **-D** option displays detailed memory-usage statistics for segments.

```

# svmon -D 404
Segid: 404
Type: working
Description: kernel extension
Address Range: 0..24580
Size of page space allocation: 0 pages ( 0.0 Mb)
Inuse: 28 frames ( 0.1 Mb)

```

Page	Frame	Pin	Ref	Mod
12294	3320	pin	ref	mod
24580	1052	pin	ref	mod
12293	52774	pin	ref	mod
24579	20109	pin	ref	mod
12292	19494	pin	ref	mod
12291	52108	pin	ref	mod
24578	50685	pin	ref	mod
12290	51024	pin	ref	mod
24577	1598	pin	ref	mod
12289	35007	pin	ref	mod
24576	204	pin	ref	mod
12288	206	pin	ref	mod
4112	53007	pin		mod

4111	53006	pin		mod
4110	53005	pin		mod
4109	53004	pin		mod
4108	53003	pin		mod
4107	53002	pin		mod
4106	53001	pin		mod
4105	53000	pin		mod
4104	52999	pin		mod
4103	52998	pin		mod
4102	52997	pin		mod
4101	52996	pin		mod
4100	52995	pin		mod
4099	52994	pin		mod
4098	52993	pin		mod
4097	52992	pin	ref	mod

The detail columns are explained as follows:

Page Specifies the index of the page within the segment.

Frame Specifies the index of the real memory frame that the page resides in.

Pin Specifies a flag indicating whether the page is pinned.

Ref Specifies a flag indicating whether the page's reference bit is on.

Mod Specifies a flag indicating whether the page is modified.

The size of page space allocation is 0 because all the pages are pinned in real memory.

An example output from AIX 4.3.3 and later, is very similar to the following:

```
# svmon -D 629 -b

Segid: 629
Type: working
Address Range: 0..77
Size of page space allocation: 7 pages ( 0.0 Mb)
Virtual: 11 frames ( 0.0 Mb)
Inuse: 7 frames ( 0.0 Mb)
```

Page	Frame	Pin	Ref	Mod
0	32304	N	Y	Y
3	32167	N	Y	Y
7	32321	N	Y	Y
8	32320	N	Y	Y
5	32941	N	Y	Y
1	48357	N	N	Y
77	47897	N	N	Y

The **-b** flag shows the status of the reference and modified bits of all the displayed frames. After it is shown, the reference bit of the frame is reset. When used with the **-i** flag, it detects which frames are accessed between each interval.

Note: Use this flag with caution because of its performance impacts.

List of Top Memory Usage of Segments

The **-S** option is used to sort segments by memory usage and to display the memory-usage statistics for the top memory-usage segments. If count is not specified, then a count of 10 is implicit. The following command sorts system and non-system segments by the number of pages in real memory and prints out the top 10 segments of the resulting list.

```
# svmon -Sau

Segid Type Description          Inuse  Pin  Pgspace  Address Range
  0  work  kernel                1990  1408    3722  0..32767 : 32768..65535

Correlating svmon and vmstat Outputs

There are some relationships between the **svmon** and **vmstat** outputs. The **svmon** report of AIX 4.3.2 follows (the example is the same with AIX 4.3.3 and later, although the output format is different):

```
# svmon -G
      m e m o r y           i n u s e           p i n           p g   s p a c e
size inuse free pin work pers clnt work pers clnt size inuse
16384 16254 130 2016 11198 2537 2519 2016 0 0 40960 13392
```

The **vmstat** command was run in a separate window while the **svmon** command was running. The **vmstat** report follows:

```
# vmstat 5
kthr  memory          page          faults          cpu
-----
r  b  avm  fre  re  pi  po  fr  sr  cy  in  sy  cs  us  sy  id  wa
0  0 13392 130  0  0  0  0  2  0 125 140 36  2  1 97  0
0  0 13336 199  0  0  0  0  0  0 145 14028 38 11 22 67  0
0  0 13336 199  0  0  0  0  0  0 141  49 31  1  1 98  0
0  0 13336 199  0  0  0  0  0  0 142  49 32  1  1 98  0
0  0 13336 199  0  0  0  0  0  0 145  49 32  1  1 99  0
0  0 13336 199  0  0  0  0  0  0 163  49 33  1  1 92  6
0  0 13336 199  0  0  0  0  0  0 142  49 32  0  1 98  0
```

The global **svmon** report shows related numbers. The **vmstat** fre column relates to the **svmon** memory free column. The number that **vmstat** reports as Active Virtual Memory (avm) is reported by the **svmon** command as pg space inuse (13392).

The **vmstat** avm column provides the same figures as the pg space inuse column of the **svmon** command except starting with AIX 4.3.2 where Deferred Page Space Allocation is used. In that case, the **svmon**

command shows the number of pages actually paged out to paging space whereas the **vmstat** command shows the number of virtual pages accessed but not necessarily paged out (see Looking at Paging Space and Virtual Memory).

Correlating svmon and ps Outputs

There are some relationships between the **svmon** and **ps** outputs. The **svmon** report of AIX 4.3.2 follows (the example is the same with AIX 4.3.3 and later, although the output format is different):

```
# svmon -P 7226
```

```

Pid                Command          Inuse          Pin           Pgspace
7226               telnetd         936            1             69

Pid: 7226
Command: telnetd

Segid  Type  Description          Inuse  Pin  Pgspace  Address Range
 828   pers  /dev/hd2:15333       0      0      0      0..0
1d3e   work  lib data             0      0     28     0..559
 909   work  shared library text  930    0      8     0..65535
1cbb   work  sreg[3]              0      0      1     0..0
1694   work  private              6      1     32     0..24 : 65310..65535
12f6   pers  code,/dev/hd2:69914  0      0      0     0..11

```

Compare with the **ps** report, which follows:

```
# ps v 7226
  PID  TTY  STAT  TIME  PGIN  SIZE  RSS  LIM  TSIZ  TRS  %CPU  %MEM  COMMAND
 7226  -  A    0:00  51   240   24  32768  33    0  0.0  0.0  telnetd

```

SIZE refers to the virtual size in KB of the data section of the process (in paging space). This number is equal to the number of working segment pages of the process that have been touched (that is, the number of paging-space pages that have been allocated) times 4. It must be multiplied by 4 because pages are in 4 K units and SIZE is in 1 K units. If some working segment pages are currently paged out, this number is larger than the amount of real memory being used. The SIZE value (240) correlates with the Pgspace number from the **svmon** command for private (32) plus lib data (28) in 1 K units.

RSS refers to the real memory (resident set) size in KB of the process. This number is equal to the sum of the number of working segment and code segment pages in memory times 4. Remember that code segment pages are shared among all of the currently running instances of the program. If 26 **ksh** processes are running, only one copy of any given page of the **ksh** executable program would be in memory, but the **ps** command would report that code segment size as part of the RSS of each instance of the **ksh** program. The RSS value (24) correlates with the Inuse numbers from the **svmon** command for private (6) working-storage segments, for code (0) segments, and for lib data (0) of the process in 1-K units.

TRS refers to the size of the resident set (real memory) of text. This is the number of code segment pages times four. As was noted earlier, this number exaggerates memory use for programs of which multiple instances are running. This does not include the shared text of the process. The TRS value (0) correlates with the number of the **svmon** pages in the code segment (0) of the Inuse column in 1 K units. The TRS value can be higher than the TSIZ value because other pages, such as the XCOFF header and the loader section, may be included in the code segment.

The following calculations can be made for the values mentioned:

```

SIZE = 4 * Pgspace of (work lib data + work private)
RSS  = 4 * Inuse of (work lib data + work private + pers code)
TRS  = 4 * Inuse of (pers code)

```

Calculating the Minimum Memory Requirement of a Program

To calculate the minimum memory requirement of a program, the formula would be:

Total memory pages (4 KB units) = $T + (N * (PD + LD)) + F$

where:

- T** = Number of pages for text (shared by all users)
- N** = Number of copies of this program running simultaneously
- PD** = Number of working segment pages in process private segment
- LD** = Number of shared library data pages used by the process
- F** = Number of file pages (shared by all users)

Multiply the result by 4 to obtain the number of kilobytes required. You may want to add in the kernel, kernel extension, and shared library text segment values to this as well even though they are shared by all processes on the system. For example, some applications like CATIA and databases use very large shared library modules. Note that because we have only used statistics from a single snapshot of the process, there is no guarantee that the value we get from the formula will be the correct value for the minimum working set size of a process. To get working set size, one would need to run a tool such as the **rmss** command or take many snapshots during the life of the process and determine the average values from these snapshots (see Assessing Memory Requirements Through the **rmss** Command).

If we estimate the minimum memory requirement for the program **pacman**, shown in Finding Memory-Leaking Programs, the formula would be:

- T** = 2 (Inuse of code, /dev/lv01:12302 of pers)
- PD** = 1632 (Inuse of private of work)
- LD** = 12 (Inuse of lib data of work)
- F** = 1 (Inuse of /dev/hd2:53289 of pers)

That is: $2 + (N * (1632 + 12)) + 1$, equal to $1644 * N + 3$ in 4 KB units.

Finding Memory-Leaking Programs

A *memory leak* is a program error that consists of repeatedly allocating memory, using it, and then neglecting to free it. A memory leak in a long-running program, such as an interactive application, is a serious problem, because it can result in memory fragmentation and the accumulation of large numbers of mostly garbage-filled pages in real memory and page space. Systems have been known to run out of page space because of a memory leak in a single program.

A memory leak can be detected with the **svmon** command, by looking for processes whose working segment continually grows. A leak in a kernel segment can be caused by an mbuf leak or by a device driver, kernel extension, or even the kernel. To determine if a segment is growing, use the **svmon** command with the **-i** option to look at a process or a group of processes and see if any segment continues to grow.

Identifying the offending subroutine or line of code is more difficult, especially in AIXwindows applications, which generate large numbers of **malloc()** and **free()** calls. C++ provides a HeapView Debugger for analyzing/tuning memory usage and leaks. Some third-party programs exist for analyzing memory leaks, but they require access to the program source code.

Some uses of the **realloc()** subroutine, while not actually programming errors, can have the same effect as a memory leak. If a program frequently uses the **realloc()** subroutine to increase the size of a data

area, the working segment of the process can become increasingly fragmented if the storage released by the **realloc()** subroutine cannot be reused for anything else.

Use the **disclaim()** system call and **free()** call to release memory that is no longer required. The **disclaim()** system call must be called before the **free()** call. It wastes CPU time to free memory after the last **malloc()** call, if the program will finish soon. When the program terminates, its working segment is destroyed and the real memory page frames that contained working segment data are added to the free list. The following example is a memory-leaking program; its Inuse, Pgspace, and Address Range of the private working segment are continually growing.

An output example from AIX 4.3.2 follows (the example is the same with AIX 4.3.3 and later, although the output format is different):

```
# svmon -P 19556 -i 1 3
  Pid          Command      Inuse      Pin      Pgspace
19556          pacman        3085        1        1580
Pid: 19556
Command: pacman
Segid Type Description      Inuse      Pin      Pgspace  Address Range

```

Assessing Memory Requirements Through the **rmss** Command

The **rmss** (Reduced-Memory System Simulator) command provides you with a means to simulate different sizes of real memories that are smaller than your actual machine, without having to extract and replace memory boards. Moreover, the **rmss** command provides a facility to run an application over a range of memory sizes, displaying, for each memory size, performance statistics such as the response time of the application and the amount of paging. The **rmss** command is designed to help you answer the question: “How many megabytes of real memory does a system need to run the operating system and a given application with an acceptable level of performance?”. In the multiuser context, it is designed to help you answer the question: “How many users can run this application simultaneously in a machine with *X* megabytes of real memory?”

The main use for the **rmss** command is as a capacity planning tool, to determine how much memory a workload needs. It can also be used as a problem determination tool, particularly for those cases where having more memory degrades performance.

To determine whether the **rmss** command is installed and available, run the following command:

```
# ls1pp -lI perfagent.tools
```

It is important to keep in mind that the memory size simulated by the **rmss** command is the total size of the machine's real memory, including the memory used by the operating system and any other programs that may be running. It is not the amount of memory used specifically by the application itself. Because of the performance degradation it can cause, the **rmss** command can be used only by a root user or a member of the system group.

Two Styles of Using rmss

The **rmss** command can be invoked in two ways:

1. To change the memory size and exit.
2. As a driver program, which executes a specified application multiple times over a range of memory sizes and displays important statistics that describe the application's performance at each memory size.

The first invocation technique is useful when you want to get the look and feel of how your application performs at a given system memory size, when your application is too complex to be expressed as a single command, or when you want to run multiple instances of the application. The second invocation technique is appropriate when you have an application that can be invoked as an executable program or shell script file.

Note: Before using the **rmss** command, run the command **/usr/samples/kernel/schedtune -h 0** to turn off VMM memory-load control (see Tuning VMM Memory Load Control with the schedtune Command). Otherwise, VMM memory-load control may interfere with your measurements at small memory sizes. When your experiments are complete, reset the memory load control parameters to the values that are typically in effect on your system (if you typically use the default parameters, use **/usr/samples/kernel/schedtune -D**).

Using rmss to Change the Memory Size and Exit

To change the memory size and exit, use the **-c** flag. For example, to change the memory size to 128 MB, use the following:

```
# rmss -c 128
```

The memory size is an integer or decimal fraction number of megabytes (for example, 128.25). Additionally, the size must be between 8 MB and the amount of physical real memory in your machine. Depending on the hardware and software configuration, the **rmss** command may not be able to change the memory size to small sizes, because of the size of inherent system structures such as the kernel. When the **rmss** command is unable to change to a given memory size, it displays an error message.

The **rmss** command reduces the effective memory size of a system by stealing free page frames from the list of free frames that is maintained by the VMM. The stolen frames are kept in a pool of unusable frames and are returned to the free frame list when the effective memory size is to be increased. Also, the **rmss** command dynamically adjusts certain system variables and data structures that must be kept proportional to the effective size of memory.

It may take a short while (up to 15 to 20 seconds) to change the memory size. In general, the more you want to reduce the memory size, the longer the **rmss** command takes to complete. When successful, the **rmss** command responds with the following message:

```
Simulated memory size changed to 128.00 Mb.
```

To display the current memory size, use the **-p** flag, as follows:

```
# rmss -p
```

The **rmss** output is as follows:

```
Simulated memory size is 128.00 Mb.
```

Finally, if you want to reset the memory size to the actual memory size of the machine, use the **-r** flag, as follows:

```
# rmss -r
```

No matter what the current simulated memory size, using the **-r** flag sets the memory size to be the physical real memory size of the machine. A side effect of the **rmss -r** command is that the related **vmtune** parameters are also reset to their corresponding defaults.

Because this example was run on a 256 MB machine, the **rmss** command responded as follows:

```
Simulated memory size changed to 256.00 Mb.
```

Note: The **rmss** command reports usable real memory. On machines that contain bad memory or memory that is in use, the **rmss** command reports the amount of real memory as the amount of physical real memory minus the memory that is bad or in use by the system. For example, the **rmss -r** command might report:

```
Simulated memory size changed to 79.9062 Mb.
```

This could be a result of some pages being marked bad or a result of a device that is reserving some pages for its own use (and thus not available to the user).

Using the -c, -p, and -r Flags: The **-c**, **-p** and **-r** flags of the **rmss** command have an advantage over the other options in that they allow you to experiment with complex applications that cannot be expressed as a single executable program or shell script file. On the other hand, the **-c**, **-p**, and **-r** options have a disadvantage in that they force you to do your own performance measurements. Fortunately, you can use the command **vmstat -s** to measure the paging-space activity that occurred while your application ran.

By running the command **vmstat -s**, running your application, then running the command **vmstat -s** again, and subtracting the number of paging-space page-ins before from the number of paging-space page-ins after, you can determine the number of paging-space page-ins that occurred while your program ran. Furthermore, by timing your program, and dividing the number of paging-space page-ins by the program's elapsed run time, you can obtain the average paging-space page-in rate.

It is also important to run the application multiple times at each memory size, for two reasons:

- When changing memory size, the **rmss** command often clears out a lot of memory. Thus, the first time you run your application after changing memory sizes it is possible that a substantial part of the run time may be due to your application reading files into real memory. But, since the files may remain in memory after your application terminates, subsequent executions of your application may result in substantially shorter elapsed times.
- To get a feel for the average performance of the application at that memory size. It is impossible to duplicate the system state each time your application runs. Because of this, the performance of your application can vary significantly from run to run.

To summarize, consider the following set of steps as a desirable way to invoke the **rmss** command:

```
while there are interesting memory sizes to investigate:
{
  change to an interesting memory size using rmss -c;
  run the application once as a warm-up;
  for a couple of iterations:
  {
    use vmstat -s to get the "before" value of paging-space page ins;
```

```

run the application, while timing it;
use vmstat -s to get the "after" value of paging-space page ins;
subtract the "before" value from the "after" value to get the
    number of page ins that occurred while the application ran;
divide the number of paging-space page ins by the response time
    to get the paging-space page-in rate;
}
}
run rmss -r to restore the system to normal memory size (or reboot)

```

The calculation of the (after - before) paging I/O numbers can be automated by using the **vmstatit** script described in Determining Whether the Problem is Related to Disk or Memory.

Using **rmss** to Run a Command over a Range of Memory Sizes

The **-s**, **-f**, **-d**, **-n**, and **-o** flags are used in combination to invoke the **rmss** command as a driver program. As a driver program, the **rmss** command executes a specified application over a range of memory sizes and displays statistics describing the application's performance at each memory size. The syntax for this invocation style of the **rmss** command is as follows:

```

rmss [ -s smemsize ] [ -f fmemsize ] [ -d memdelta ]
     [ -n numiterations ] [ -o outputfile ] command

```

Each of the following flags is discussed in detail below. The **-s**, **-f**, and **-d** flags are used to specify the range of memory sizes.

- n** This flag is used to specify the number of times to run and measure the command at each memory size.
- o** This flag is used to specify the file into which to write the **rmss** report, while **command** is the application that you wish to run and measure at each memory size.
- s** This flag specifies the starting size.
- f** This flag specifies the final size.
- d** This flag specifies the difference between sizes.

All values are in integer or decimal fractions of megabytes. For example, if you wanted to run and measure a command at sizes 256, 224, 192, 160 and 128 MB, you would use the following combination:

```
-s 256 -f 128 -d 32
```

Likewise, if you wanted to run and measure a command at 128, 160, 192, 224, and 256 MB, you would use the following combination:

```
-s 128 -f 256 -d 32
```

If the **-s** flag is omitted, the **rmss** command starts at the actual memory size of the machine. If the **-f** flag is omitted, the **rmss** command finishes at 8 MB. If the **-d** flag is omitted, there is a default of 8 MB between memory sizes.

What values should you choose for the **-s**, **-f**, and **-d** flags? A simple choice would be to cover the memory sizes of systems that are being considered to run the application you are measuring. However, increments of less than 8 MB can be useful, because you can get an estimate of how much space you will have when you settle on a given size. For instance, if a given application thrashes at 120 MB but runs without page-ins at 128 MB, it would be useful to know where within the 120 to 128 MB range the application starts thrashing. If it starts at 127 MB, you may want to consider configuring the system with more than 128 MB of memory, or you may want to try to modify the application so that there is more space. On the other hand, if the thrashing starts at 121 MB, you know that you have enough space with a 128 MB machine.

The **-n** flag is used to specify how many times to run and measure the command at each memory size. After running and measuring the command the specified number of times, the **rmss** command displays

statistics describing the average performance of the application at that memory size. To run the command 3 times at each memory size, you would use the following:

```
-n 3
```

If the **-n** flag is omitted, the **rmss** command determines during initialization how many times your application must be run to accumulate a total run time of 10 seconds. The **rmss** command does this to ensure that the performance statistics for short-running programs will not be significantly skewed by outside influences, such as daemons.

Note: If you are measuring a very brief program, the number of iterations required to accumulate 10 seconds of CPU time can be very large. Because each execution of the program takes a minimum of about 2 elapsed seconds of **rmss** overhead, specify the **-n** parameter explicitly for short programs.

What are good values to use for the **-n** flag? If you know that your application takes much more than 10 seconds to run, you can specify **-n 1** so that the command is run twice, but measured only once at each memory size. The advantage of using the **-n** flag is that the **rmss** command will finish sooner because it will not have to spend time during initialization to determine how many times to run your program. This can be particularly valuable when the command being measured is long-running and interactive.

It is important to note that the **rmss** command always runs the command once at each memory size as a warm-up before running and measuring the command. The warm-up is needed to avoid the I/O that occurs when the application is not already in memory. Although such I/O does affect performance, it is not necessarily due to a lack of real memory. The warm-up run is not included in the number of iterations specified by the **-n** flag.

The **-o** flag is used to specify a file into which to write the **rmss** report. If the **-o** flag is omitted, the report is written into the file **rmss.out**.

Finally, **command** is used to specify the application to be measured. It can be an executable program or shell script, with or without command-line arguments. There are some limitations on the form of the command however. First, it cannot contain the redirection of input or output (for example, **foo > output** or **foo < input**). This is because the **rmss** command treats everything to the right of the command name as an argument to the command. To redirect, place the command in a shell script file.

Usually, if you want to store the **rmss** output in a specific file, use the **-o** option. If you want to redirect the standard output of the **rmss** command (for example, to concatenate it to the end of an existing file) then use the Korn shell to enclose the **rmss** invocation in parentheses, as follows:

```
# (rmss -s 24 -f 8 foo) >> output
```

Interpreting rmss Results

The Report Generated for the foo Program example was produced by running the **rmss** command on an actual application program, although the name of the program has been changed to foo for anonymity. The specific command that would have been used to generate the report is as follows:

```
# rmss -s 16 -f 8 -d 1 -n 1 -o rmss.out foo
```

Report Generated for the foo Program

```
Hostname: widgeon.austin.ibm.com
Real memory size: 16.00 Mb
Time of day: Thu Jan 6 19:04:04 2000
Command: foo
```

Simulated memory size initialized to 16.00 Mb.

Number of iterations per memory size = 1 warm-up + 1 measured = 2.

Memory size (megabytes)	Avg. Pageins	Avg. Response Time (sec.)	Avg. Pagein Rate (pageins / sec.)
----------------------------	--------------	------------------------------	--------------------------------------

Memory size (MB)	Avg. Pageins	Avg. Response Time (sec.)	Avg. Pagein Rate (pageins / sec.)
16.00	115.0	123.9	0.9
15.00	112.0	125.1	0.9
14.00	179.0	126.2	1.4
13.00	81.0	125.7	0.6
12.00	403.0	132.0	3.1
11.00	855.0	141.5	6.0
10.00	1161.0	146.8	7.9
9.00	1529.0	161.3	9.5
8.00	2931.0	202.5	14.5

The report consists of four columns. The leftmost column gives the memory size, while the Avg. Pageins column gives the average number of page-ins that occurred when the application was run at that memory size. It is important to note that the Avg. Pageins column refers to all page-in operations, including code, data, and file reads, from all programs, that completed while the application ran. The Avg. Response Time column gives the average amount of time it took the application to complete, while the Avg. Pagein Rate column gives the average rate of page-ins.

Concentrate on the Avg. Pagein Rate column. From 16 MB to 13 MB, the page-in rate is relatively small (< 1.5 page-ins per second). However, from 13 MB to 8 MB, the page-in rate grows gradually at first, and then rapidly as 8 MB is reached. The Avg. Response Time column has a similar shape: relatively flat at first, then increasing gradually, and finally increasing rapidly as the memory size is decreased to 8 MB.

Here, the page-in rate actually decreases when the memory size changes from 14 MB (1.4 page-ins per second) to 13 MB (0.6 page-ins per second). This is not cause for alarm. In an actual system, it is impossible to expect the results to be perfectly smooth. The important point is that the page-in rate is relatively low at both 14 MB and 13 MB.

Finally, you can make a couple of deductions from the report. First, if the performance of the application is deemed unacceptable at 8 MB (as it probably would be), then adding memory would enhance performance significantly. Note that the response time rises from approximately 124 seconds at 16 MB to 202 seconds at 8 MB, an increase of 63 percent. On the other hand, if the performance is deemed unacceptable at 16 MB, adding memory will not enhance performance much, because page-ins do not slow the program appreciably at 16 MB.

Report for a 16 MB Remote Copy

The following example illustrates a report that was generated (on a client machine) by running the **rmss** command on a command that copied a 16 MB file from a remote (server) machine through NFS.

```

Hostname: xray.austin.ibm.com
Real memory size: 48.00 Mb
Time of day: Mon Jan 10 18:16:42 2000
Command: cp /mnt/a16Mfile /dev/null

```

Simulated memory size initialized to 48.00 Mb.

Number of iterations per memory size = 1 warm-up + 4 measured = 5.

Memory size (megabytes)	Avg. Pageins	Avg. Response Time (sec.)	Avg. Pagein Rate (pageins / sec.)
48.00	0.0	2.7	0.0
40.00	0.0	2.7	0.0
32.00	0.0	2.7	0.0
24.00	1520.8	26.9	56.6
16.00	4104.2	67.5	60.8
8.00	4106.8	66.9	61.4

Note that the response time and page-in rate in this report start relatively low, rapidly increase at a memory size of 24 MB, and then reach a plateau at 16 and 8 MB. This report shows the importance of choosing a wide range of memory sizes when you use the **rmss** command. If this user had only looked at

memory sizes from 24 MB to 8 MB, he or she might have missed an opportunity to configure the system with enough memory to accommodate the application without page-ins.

Hints for Using the **-s**, **-f**, **-d**, **-n**, and **-o** Flags

One helpful feature of the **rmss** command, when used in this way, is that it can be terminated (by the interrupt key, Ctrl-C by default) without destroying the report that has been written to the output file. In addition to writing the report to the output file, this causes the **rmss** command to reset the memory size to the physical memory size of the machine.

You can run the **rmss** command in the background, even after you have logged out, by using the **nohup** command. To do this, precede the **rmss** command by the **nohup** command, and follow the entire command with an **&** (ampersand), as follows:

```
# nohup rmss -s 48 -f 8 -o foo.out foo &
```

Guidelines to Consider When Running the **rmss** Command

No matter which **rmss** invocation style you are using, it is important to re-create the end-user environment as closely as possible. For instance, are you using the same model CPU, the same model disks, the same network? Will the users have application files mounted from a remote node via NFS or some other distributed file system? This last point is particularly important, because pages from remote files are treated differently by the VMM than pages from local files.

Likewise, it is best to eliminate any system activity that is not related to the desired system configuration or the application you are measuring. For instance, you do not want to have people working on the same machine as the **rmss** command unless they are running part of the workload you are measuring.

Note: You cannot run multiple invocations of the **rmss** command simultaneously.

When you have completed all runs of the **rmss** command, it is best to shut down and reboot the system. This will remove all changes that the **rmss** command has made to the system and will restore the VMM memory load control parameters to their typical settings.

Tuning VMM Memory Load Control with the **schedtune** Command

The VMM memory load control facility, described in VMM Memory Load Control Facility, protects an overloaded system from thrashing.

For early versions of the operating system, if a large number of processes hit the system at the same time, memory became overcommitted and thrashing occurred, causing performance to degrade rapidly. A memory-load control mechanism was developed that could detect thrashing. Certain parameters affect the function of the load control mechanism.

With the **schedtune** command, the root user can affect the criteria used to determine thrashing, the criteria used to determine which processes to suspend, the length of time to wait after thrashing ends before reactivating processes, the minimum number of processes exempt from suspension, or reset values to the defaults. To determine whether the **schedtune** command is installed and available, run the following command:

```
# ls1pp -lI bos.adt.samples
```

Memory Load Control Tuning

Memory load control is intended to smooth out infrequent peaks in load that might otherwise cause the system to thrash. It trades multiprogramming for throughput and is not intended to act continuously in a configuration that has too little RAM to handle its normal workload. The design was made for batch jobs and is not very discriminating. The AIX Workload Manager provides a better solution to protect critical tasks.

The correct solution to a fundamental, persistent RAM shortage is to add RAM, not to experiment with memory load control in an attempt to trade off response time for memory. The situations in which the memory-load-control facility may really need to be tuned are those in which there is more RAM, not less than the defaults were chosen for. An example would be configurations in which the defaults are too conservative.

You should not change the memory load control parameter settings unless your workload is consistent and you believe the default parameters are ill-suited to your workload.

The default parameter settings shipped with the system are always in force unless changed. The default values of these parameters have been chosen to "fail safe" across a wide range of workloads. Changed parameters last only until the next system boot. All memory load control tuning activities must be done by the root user. The system administrator can use the **schedtune** command to change the parameters to tune the algorithm to a particular workload or to disable it entirely. The source and object code of the **schedtune** command are in **/usr/samples/kernel**.

Note: The **schedtune** command is in the samples directory because it is very VMM-implementation dependent. The **schedtune** code that accompanies each release of the operating system is tailored specifically to the VMM in that release. Running the **schedtune** command from one release on a different release might result in an operating-system failure. It is also possible that the functions of the **schedtune** command may change from release to release. Do not propagate shell scripts or **/etc/inittab** entries that include the **schedtune** command to a new release without checking the **schedtune** documentation for the new release to make sure that the scripts will still have the desired effect.

The **schedtune -?** command provides a terse description of the flags and options. A **schedtune** invocation with no flags displays the current parameter settings, as follows:

```
# /usr/samples/kernel/schedtune

THRASH          SUSP          FORK          SCHED
-h  -p  -m      -w      -e      -f      -d      -r      -t      -s
SYS  PROC  MULTI  WAIT  GRACE  TICKS  SCHED_D  SCHED_R  TIMESLICE  MAXSPIN
  0   4    2     1    2     10    16     16     1     16384

    CLOCK  SCHED_FIFO2  IDLE MIGRATION  FIXED_PRI
    -c      -a          -b          -F
%usDELTA  AFFINITY_LIM  BARRIER/16  GLOBAL(1)
    100        7           4           0
```

The first five parameters specify the thresholds for the memory load control algorithm. These parameters set rates and thresholds for the algorithm. If the algorithm shows that RAM is overcommitted, the PROC (-p), MULTI (-m), WAIT (-w), and GRACE (-e) values are used. Otherwise, these values are ignored. If memory load control is disabled, these latter values are not used.

After a tuning experiment, memory load control can be reset to its default characteristics by executing the command **schedtune -D**.

When you have determined the number of processes that ought to be able to run in your system during periods of peak activity, you can add a **schedtune** command at the end of the **/etc/inittab** file, which ensures that it will be run each time the system is booted, overriding the defaults that would otherwise take effect with a reboot. For example, an appropriate **/etc/inittab** line for raising the minimum level of multiprogramming to 4 on an AIX Version 4 system would be as follows:

```
schedtune:2:wait:/usr/samples/kernel/schedtune -m 4
```

Remember, do not propagate this line to a new release of the operating system without a check of the operating system documentation.

While it is possible to vary other parameters that control the suspension rate of processes and the criteria by which individual processes are selected for suspension, it is impossible to predict with any confidence the effect of such changes on a particular configuration and workload. Great caution should be exercised if memory load control parameter adjustments other than those discussed here are considered.

The *h* Parameter

The *h* parameter controls the threshold defining memory overcommitment. Memory load control attempts to suspend processes when this threshold is exceeded during any one-second period. The threshold is a relationship between two direct measures: the number of pages written to paging space in the last second (*po*) and the number of page steals occurring in the last second (*fr*). You can see both these values in the **vmstat** output. The number of page writes is usually much less than the number of page steals. Memory is overcommitted when the following is true:

$$po/fr > 1/h \text{ or } po * h > fr$$

The command **schedtune -h 0** effectively disables memory load control. If a system has at least 128 MB of memory, the default value is 0, otherwise the default value is 6. With at least 128 MB of RAM, the normal VMM algorithms usually correct thrashing conditions on the average more efficiently than by using memory load control.

In some specialized situations, it might be appropriate to disable memory load control from the outset. For example, if you are using a terminal emulator with a time-out feature to simulate a multiuser workload, memory load control intervention may result in some responses being delayed long enough for the process to be killed by the time-out feature. Another example is, if you are using the **rmss** command to investigate the effects of reduced memory sizes, disable memory load control to avoid interference with your measurement.

If disabling memory load control results in more, rather than fewer, thrashing situations (with correspondingly poorer responsiveness), then memory load control is playing an active and supportive role in your system. Tuning the memory load control parameters then may result in improved performance or you may need to add RAM.

A lower value of *h* raises the thrashing detection threshold; that is, the system is allowed to come closer to thrashing before processes are suspended. Regardless of the system configuration, when the above *po/fr* fraction is low, thrashing is unlikely.

To alter the threshold to 4, enter the following:

```
# /usr/samples/kernel/schedtune -h 4
```

In this way, you permit the system to come closer to thrashing before the algorithm starts suspending processes.

The *p* Parameter

The *p* parameter determines whether a process is eligible for suspension and is used to set a threshold for the ratio of two measures that are maintained for every process: the number of repages (*r*) and the number of page faults that the process has accumulated in the last second (*f*). A high ratio of repages to page faults means the individual process is thrashing. A process is considered eligible for suspension (it is thrashing or contributing to overall thrashing) when the following is true:

$$r/f > 1/p \text{ or } r * p > f$$

The default value of *p* is 4, meaning that a process is considered to be thrashing (and a candidate for suspension) when the fraction of repages to page faults over the last second is greater than 25 percent. A low value of *p* results in a higher degree of individual process thrashing being allowed before a process is eligible for suspension.

To disable processes from being suspended by the memory load control, do the following:

```
# /usr/samples/kernel/schedtune -p 0
```

Note that fixed-priority processes and kernel processes are exempt from being suspended.

The *m* Parameter

The *m* parameter determines a lower limit for the degree of multiprogramming, which is defined as the number of active processes. Active processes are those that can be run and are waiting for page I/O. Processes that are waiting for events and processes suspended are not considered active nor is the wait process considered active.

Setting the minimum multiprogramming level, *m*, effectively keeps *m* processes from being suspended. Suppose a system administrator knows that at least ten processes must always be resident and active in RAM for successful performance, and suspects that memory load control was too vigorously suspending processes. If the command **schedtune -m 10** was issued, the system would never suspend so many processes that fewer than ten were competing for memory. The *m* parameter does not count:

- The kernel processes
- Processes that have been pinned in RAM with the **plock()** system call
- Fixed-priority processes with priority values less than 60
- Processes awaiting events

The system default of *m*=2 ensures that the kernel, all pinned processes, and two user processes will always be in the set of processes competing for RAM.

While *m*=2 is appropriate for a desktop, single-user configuration, it is frequently too small for larger, multiuser, or server configurations with large amounts of RAM.

If the system you are installing is larger than 32 MB, but less than 128 MB, and is expected to support more than five active users at one time, consider raising the minimum level of multiprogramming of the VMM memory-load-control mechanism.

As an example, if your conservative estimate is that four of your most memory-intensive applications should be able to run simultaneously, leaving at least 16 MB for the operating system and 25 percent of real memory for file pages, you could increase the minimum multiprogramming level from the default of 2 to 4 with the following command:

```
# /usr/samples/kernel/schedtune -m 4
```

On these systems, setting *m* to 4 or 6 may result in the best performance. Lower values of *m*, while allowed, mean that at times as few as one user process may be active.

When the memory requirements of the thrashing application are known, the *m* value can be suitably chosen. Suppose thrashing is caused by numerous instances of one application of size *M*. Given the system memory size *N*, the *m* parameter should be set to a value close to *N*/*M*. Setting *m* too low would unnecessarily limit the number of processes that could be active at the same time.

The *w* Parameter

The *w* parameter controls the number of one-second intervals during which the *po/fr* fraction (explained in the The *h* Parameter) must remain below 1/*h* before suspended processes are reactivated. The default value of one second is close to the minimum value allowed, which is zero. A value of one second aggressively attempts to reactivate processes as soon as a one-second safe period has occurred. Large values of *w* run the risk of unnecessarily poor response times for suspended processes while the processor is idle for lack of active processes to run.

To alter the wait time to reactivate processes after two seconds, enter the following:

```
# /usr/samples/kernel/schedtune -w 2
```

The e Parameter

Each time a suspended process is reactivated, it is exempt from suspension for a period of *e* elapsed seconds. This ensures that the high cost (in disk I/O) of paging in the pages of a suspended process results in a reasonable opportunity for progress. The default value of *e* is 2 seconds.

To alter this parameter, enter the following:

```
# /usr/samples/kernel/schedtune -e 1
```

Suppose thrashing is caused occasionally by an application that uses lots of memory but runs for about *T* seconds. The default system setting for *e* (2 seconds) would probably cause this application swapping in and out *T/2* times on a busy system. In this case, resetting *e* to a longer time would help this application to progress. System performance would improve when this offending application is pushed through quickly.

Tuning VMM Page Replacement with the vmtune Command

The memory management algorithm, discussed in Real-Memory Management, tries to keep the size of the free list and the percentage of real memory occupied by persistent segment pages within specified bounds. These bounds can be altered with the **vmtune** command, which can only be run by the root user. Changes made by this tool remain in effect until the next reboot of the system. To determine whether the **vmtune** command is installed and available, run the following command:

```
# ls1pp -lI bos.adt.samples
```

Note: The **vmtune** command is in the samples directory because it is very VMM-implementation dependent. The **vmtune** code that accompanies each release of the operating system is tailored specifically to the VMM in that release. Running the **vmtune** command from one release on a different release might result in an operating-system failure. It is also possible that the functions of **vmtune** may change from release to release. Do not propagate shell scripts or **/etc/inittab** entries that include the **vmtune** command to a new release without checking the **vmtune** documentation for the new release to make sure that the scripts will still have the desired effect.

Executing the **vmtune** command on AIX 4.3.3 with no options results in the following output:

```
# /usr/samples/kernel/vmtune
vmtune: current values:
  -p      -P      -r      -R      -f      -F      -N      -W
minperm  maxperm  minpgahead  maxpgahead  minfree  maxfree  pd_npages  maxrandwrt
 52190   208760      2           8          120     128     524288      0

  -M      -w      -k      -c      -b      -B      -u      -l      -d
maxpin  npswarn  npskill  numclust  numfsbufs  hd_pbuf_cnt  lvm_bufcnt  lrubucket  defps
209581   4096    1024      1         93         96         9       131072     1

  -s      -n      -S      -h
sync_release_ilock  nokillroot  v_pinshm  strict_maxperm
 0                 0          0          0

number of valid memory pages = 261976  maxperm=79.7% of real memory
maximum pinable=80.0% of real memory  minperm=19.9% of real memory
number of file memory pages = 19772   numperm=7.5% of real memory
```

The output shows the current settings for all the parameters.

Choosing minfree and maxfree Settings

The purpose of the free list is to keep track of real-memory page frames released by terminating processes and to supply page frames to requestors immediately, without forcing them to wait for page steals and the accompanying I/O to complete. The **minfree** limit specifies the free-list size below which page stealing to replenish the free list is to be started. The **maxfree** parameter is the size above which stealing will end.

The objectives in tuning these limits are to ensure that:

- Any activity that has critical response-time objectives can always get the page frames it needs from the free list.
- The system does not experience unnecessarily high levels of I/O because of premature stealing of pages to expand the free list.

The default value of **minfree** and **maxfree** depend on the memory size of the machine. The default value of **maxfree** is determined by this formula:

$\text{maxfree} = \text{minimum} (\# \text{ of memory pages}/128, 128)$

By default the **minfree** value is the value of **maxfree** - 8. However, the difference between **minfree** and **maxfree** should always be equal to or greater than **maxpgahead**. Or in other words, the value of **maxfree** should always be greater than or equal to **minfree** plus the size of **maxpgahead**. The **minfree/maxfree** values will be different if there is more than one memory pool. Memory pools were introduced in AIX 4.3.3 for MP systems with large amounts of RAM. Each memory pool will have its own **minfree/maxfree** which are determined by the previous formulas, but the **minfree/maxfree** values shown by the **vm tune** command will be the sum of the **minfree/maxfree** for all memory pools.

Remember, that **minfree** pages in some sense are wasted, because they are available, but not in use. If you have a short list of the programs you want to run fast, you can investigate their memory requirements with the **svmon** command (see Determining How Much Memory Is Being Used), and set **minfree** to the size of the largest. This technique risks being too conservative because not all of the pages that a process uses are acquired in one burst. At the same time, you might be missing dynamic demands that come from programs not on your list that may lower the average size of the free list when your critical programs run.

A less precise but more comprehensive tool for investigating an appropriate size for **minfree** is the **vmstat** command. The following is a portion of a **vmstat** command output obtained while running an C compilation on an otherwise idle system.

```
# vmstat 1
kthr      memory          page                faults                cpu
-----
r  b   avm    fre  re  pi  po  fr  sr  cy  in  sy  cs  us  sy  id  wa
0  0  3085  118  0  0  0  0  0  0 115  2  19  0  0 99  0
0  0  3086  117  0  0  0  0  0  0 119 134 24  1  3 96  0
2  0  3141   55  2  0  6 24 98  0 175 223 60  3  9 54 34
0  1  3254   57  0  0  6 176 814 0 205 219 110 22 14  0 64
0  1  3342   59  0  0 42 104 249 0 163 314 57 43 16  0 42
1  0  3411   78  0  0 49 104 169 0 176 306 51 30 15  0 55
1  0  3528  160  1  0 10 216 487 0 143 387 54 50 22  0 27
1  0  3627   94  0  0  0  72 160 0 148 292 79 57  9  0 34
1  0  3444  327  0  0  0  64 102 0 132 150 41 82  8  0 11
1  0  3505  251  0  0  0  0  0  0 128 189 50 79 11  0 11
1  0  3550  206  0  0  0  0  0  0 124 150 22 94  6  0  0
1  0  3576  180  0  0  0  0  0  0 121 145 30 96  4  0  0
0  1  3654  100  0  0  0  0  0  0 124 145 28 91  8  0  1
1  0  3586  208  0  0  0 40  68  0 123 139 24 91  9  0  0
```

Because the compiler has not been run recently, the code of the compiler itself must be read in. All told, the compiler acquires about 2 MB in about 6 seconds. On this 32 MB system, **maxfree** is 64 and **minfree** is 56. The compiler almost instantly drives the free list size below **minfree**, and several seconds of rapid page-stealing activity take place. Some of the steals require that dirty working segment pages be written to paging space, which shows up in the **po** column. If the steals cause the writing of dirty permanent segment pages, that I/O does not appear in the **vmstat** report (unless you have directed the **vmstat** command to report on the I/O activity of the physical volumes to which the permanent pages are being written).

This example describes a **fork()** and **exec()** environment (not an environment where a process is long lived, such as in a database) and is not intended to suggest that you set **minfree** to 500 to accommodate large compiles. It suggests how to use the **vmstat** command to identify situations in which the free list has

to be replenished while a program is waiting for space. In this case, about 2 seconds were added to the compiler execution time because there were not enough page frames immediately available. If you observe the page frame consumption of your program, either during initialization or during normal processing, you will soon have an idea of the number page frames that need to be in the free list to keep the program from waiting for memory.

If we concluded from the example above that **minfree** needed to be 128, and we had set **maxpgahead** to 16 to improve sequential performance, we would use the following **vmtune** command:

```
# /usr/samples/kernel/vmtune -f 128 -F 144
```

Tuning Memory Pools

In operating system versions later than AIX 4.3.3, the **vmtune -m** *number_of_memory_pools* command allows you to change the number of memory pools that are configured at system boot time. The **-m** flag is therefore not a dynamic change. The change is written to the kernel file if it is an MP kernel (the change is not allowed on a UP kernel). A value of 0 restores the default number of memory pools.

By default, the **vmtune -m** command writes to the file **/usr/lib/boot/unix_mp**, but this can be changed with the command **vmtune -U** *path_to_unix_file*. Before changing the kernel file, the **vmtune** command saves the original file as *name_of_original_file.sav*.

Tuning Irubucket to Reduce Memory Scanning Overhead

Tuning **Irubucket** can reduce scanning overhead on large memory systems. In AIX 4.3, a new parameter **Irubucket** was added. The page-replacement algorithm scans memory frames looking for a free frame. During this scan, reference bits of pages are reset, and if a free frame has not been found, a second scan is done. In the second scan, if the reference bit is still off, the frame will be used for a new page (page replacement).

On large memory systems, there may be too many frames to scan, so now memory is divided up into buckets of frames. The page-replacement algorithm will scan the frames in the bucket and then start over on that bucket for the second scan before moving on to the next bucket. The default number of frames in this bucket is 131072 or 512 MB of RAM. The number of frames is tunable with the command **vmtune -I**, and the value is in 4 K frames.

Choosing minperm and maxperm Settings

The operating system takes advantage of the varying requirements for real memory by leaving in memory pages of files that have been read or written. If the file pages are requested again before their page frames are reassigned, this technique saves an I/O operation. These file pages may be from local or remote (for example, NFS) file systems.

The ratio of page frames used for files versus those used for computational (working or program text) segments is loosely controlled by the **minperm** and **maxperm** values:

- If percentage of RAM occupied by file pages rises above **maxperm**, page-replacement steals only file pages.
- If percentage of RAM occupied by file pages falls below **minperm**, page-replacement steals both file and computational pages.
- If percentage of RAM occupied by file pages is between **minperm** and **maxperm**, page-replacement steals only file pages unless the number of file repages is higher than the number of computational repages.

In a particular workload, it might be worthwhile to emphasize the avoidance of file I/O. In another workload, keeping computational segment pages in memory might be more important. To understand what the ratio is in the untuned state, we use the **vmtune** command with no arguments.

```

# /usr/samples/kernel/vmtune
vmtune: current values:
  -p      -P      -r      -R      -f      -F      -N      -W
minperm  maxperm  minpgahead  maxpgahead  minfree  maxfree  pd_npages  maxrandwrt
  52190   208760     2           8           120       128       524288     0

  -M      -w      -k      -c      -b      -B      -u      -l      -d
maxpin  npswarn  npskill  numclust  numfsbufs  hd_pbuf_cnt  lvm_bufcnt  lrubucket  defps
209581   4096     1024       1         93         96         9         131072     1

  -s      -n      -S      -h
sync_release_ilock  nokillroot  v_pinshm  strict_maxperm
  0             0             0             0

number of valid memory pages = 261976  maxperm=79.7% of real memory
maximum pinable=80.0% of real memory  minperm=19.9% of real memory
number of file memory pages = 19772    numperm=7.5% of real memory

```

The default values are calculated by the following algorithm:

```

minperm (in pages) = ((number of memory frames) - 1024) * .2
maxperm (in pages) = ((number of memory frames) - 1024) * .8

```

The **numperm** value gives the number of file pages in memory, 19772. This is 7.5 percent of real memory.

If we know that our workload makes little use of recently read or written files, we may want to constrain the amount of memory used for that purpose. The following command:

```
# /usr/samples/kernel/vmtune -p 15 -P 50
```

sets **minperm** to 15 percent and **maxperm** to 50 percent of real memory. This would ensure that the VMM would steal page frames only from file pages when the ratio of file pages to total memory pages exceeded 50 percent. This should reduce the paging to page space with no detrimental effect on the persistent storage. The **maxperm** value is not a strict limit, it is only considered when the VMM needs to perform page replacement. Because of this, it is usually safe to reduce the **maxperm** value on most systems.

On the other hand, if our application frequently references a small set of existing files (especially if those files are in an NFS-mounted file system), we might want to allow more space for local caching of the file pages by using the following command:

```
# /usr/samples/kernel/vmtune -p 30 -P 90
```

NFS servers that are used mostly for reads with large amounts of RAM can benefit from increasing the value of **maxperm**. This allows more pages to reside in RAM so that NFS clients can access them without forcing the NFS server to retrieve the pages from disk again.

Another example would be a program that reads 1.5 GB of sequential file data into the working storage of a system with 2 GB of real memory. You may want to set **maxperm** to 50 percent or less, because you do not need to keep the file data in memory.

Placing a Hard Limit on Persistent File Cache with **strict_maxperm**

Starting with AIX 4.3.3, a new **vmtune** option (**-h**) called **strict_maxperm** has been added. This option, when set to 1, places a hard limit on how much memory is used for a persistent file cache by making the **maxperm** value be the upper limit for this file cache. When the upper limit is reached, the least recently used (LRU) is performed on persistent pages.

Tuning Paging-Space Thresholds

If available paging space depletes to a low level, the operating system attempts to release resources by first warning processes to release paging space and finally by killing processes if there still is not enough paging space available for the current processes.

Choosing npswarn and npskill Settings

The **npswarn** and **npskill** thresholds are used by the VMM to determine when to first warn processes and eventually when to kill processes.

These two parameters can be set through the **vmtune** command:

npswarn (-w)

Specifies the number of free paging-space pages at which the operating system begins sending the SIGDANGER signal to processes. If the **npswarn** threshold is reached and a process is handling this signal, the process can choose to ignore it or do some other action such as exit or release memory using the **disclaim()** subroutine. The default value in AIX Version 4 is determined by the following formula:

$$\text{npswarn} = \text{maximum} (512, 4 * \text{npskill})$$

The value of **npswarn** must be greater than zero and less than the total number of paging-space pages on the system. It can be changed with the command **vmtune -w**.

npskill (-k)

Specifies the number of free paging-space pages at which the operating system begins killing processes. If the **npskill** threshold is reached, a SIGKILL signal is sent to the youngest process. Processes that are handling SIGDANGER or processes that are using the early page-space allocation (paging space is allocated as soon as memory is requested) are exempt from being killed. The formula to determine the default value of **npskill** is as follows:

$$\text{npskill} = \text{maximum} (64, \text{number_of_paging_space_pages}/128)$$

The **npskill** value must be greater than zero and less than the total number of paging space pages on the system. It can be changed with the command **vmtune -k**.

nokillroot and nokilluid (-n)

By setting the **nokillroot** option to 1 with the command **vmtune -n 1**, processes owned by root will be exempt from being killed when the **npskill** threshold is reached. This option is only available in AIX 4.3.3 and 4.3.3.1.

By setting the **nokilluid** option to a nonzero value with the command **vmtune -n**, user IDs lower than this value will be exempt from being killed because of low page-space conditions. This option is only available in operating system version 4.3.3.2 and later.

Tuning the fork() Retry Interval Parameter with schedtune

If a process cannot be forked due to a lack of paging-space pages, the scheduler will retry the fork five times. In between each retry, the scheduler will delay for a default of 10 clock ticks.

The **-f** parameter of the **schedtune** command specifies the number of clock ticks to wait before retrying a failed **fork()** call. For example, if a **fork()** subroutine call fails because there is not enough space available to create a new process, the system retries the call after waiting the specified number of clock ticks. The default value is 10, and because there is one clock tick every 10 ms, the system would retry the **fork()** call every 100 ms.

If the paging space is low only due to brief, sporadic workload peaks, increasing the retry interval (such as in the following) might allow processes to delay long enough to be released:

```
# /usr/samples/kernel/schedtune -f 15
```

In this way, when the system retries the **fork()** call, there is a higher chance of success because some processes might have finished their execution and, consequently, released pages from paging space.

Choosing a Page Space Allocation Method

Three page-space allocation policies are available:

- Late Page Space Allocation (LPSA)
- Early Page Space Allocation (EPSA)
- Deferred Page Space Allocation (DPSA)

Late Page Space Allocation

Prior to AIX 4.3.2, the operating system by default used a late page-space allocation policy which means that a paging space page is only allocated when it is actually touched. Being *touched* means the page was modified somehow (for example, with the **bzero()** subroutine or if page was requested by the **calloc()** subroutine or the page was initialized to some value). With the late policy, paging space slots are allocated if RAM pages are touched, but the pages are not assigned to a particular process until that process wants to page out. Therefore, there is no guarantee that a process will always have sufficient paging space available if it needed to page out because some other process can start later and consume all of the paging space.

Early Page Space Allocation

If you want to ensure that a process will not be killed due to low paging conditions, this process can preallocate paging space by using the Early Page Space Allocation policy. This is done by setting an environment variable called **PSALLOC** to the value of **early**. This can be done from within the process or at the command line (**PSALLOC=early** command). When the process uses the **malloc()** subroutine to allocate memory, this memory will now have paging-space disk blocks reserved for this process, that is, they are reserved for this process so that there is a guarantee that if the process needed to page out, there will always be paging space slots available for it. If using early policy and if CPU savings is a concern, you may want to set another environment variable called **NODISCLAIM=true** so that each **free()** subroutine call does not also result in a **disclaim()** system call.

Deferred Page Space Allocation

A new page-space allocation policy (a modification of Late Page Space Allocation) was introduced in AIX 4.3.2: Deferred Page Space Allocation. Prior to AIX 4.3.2, a page-space disk block was allocated when a page was touched. However, this paging space may never be used, especially on systems with large real memory where paging is rare. With Deferred Page Space Allocation, the disk block allocation of paging space is delayed until it is necessary to page out the page, which results in no wasted paging space allocation. This does, however, result in additional overcommitment of paging space. On a system where enough virtual memory is accessed that paging is necessary, the amount of paging space required may be as much as was required on previously.

After a page has been paged out to paging space, the disk block is reserved for that page if that page is paged back into RAM. Therefore, the paging space percentage-used value may not necessarily reflect the number of pages only in paging space because some of it may be back in RAM as well. If the page that was paged back in is working storage of a thread, and if the thread releases the memory associated with that page or if the thread exits, then the disk block for that page is released.

Choosing between LPSA and DPSA with the vmtune Command

Running the **vmtune** command with the **-d** option enables turning on or off the Deferred Page Space Allocation in order to preserve the Late Page Space Allocation policy. A value of 1 indicates that DPSA should be on, and a value of 0 indicates that DPSA should be off. If you choose to turn DPSA off, make sure that the kernel level is at least AIX 4.3.2.6 or higher.

Looking at Paging Space and Virtual Memory

The **vmstat** command (**avm** column), **ps** command (**SIZE**, **SZ**), and other utilities report the amount of virtual memory actually accessed because with DPSA, the paging space may not get touched. The **svmon**

command (up through AIX 4.3.2) shows the amount of paging space being used, so this value may be much smaller than the `avm` value of the `vmstat` command.

It is safer to use the `lsps -s` command rather than the `lsps -a` command to look at available paging space because the command `lsps -a` only shows paging space that is actually being used. But the command `lsps -s` will include paging space being used along with paging space that was reserved using the EPSSA policy.

Using Shared Memory

By using the `shmat()` or `mmap()` subroutines, files can be explicitly mapped into memory. This avoids buffering and avoids system-call overhead. The memory areas are known as the shared memory segments or regions. Beginning with AIX 4.2.1 and only affecting 32-bit applications, segment 14 was released providing 11 shared memory segments (not including the shared library data or shared library text segments) for processes (segments 3-12 and 14). Each of these segments are 256 MB in size. Applications can read/write the file by reading/writing in the segment. Applications can avoid overhead of read/write system calls simply by manipulating pointers in these mapped segments.

Files or data can also be shared among multiple processes/threads. However, this requires synchronization between these processes/threads and its handling is up to the application. Typical use is by database applications for use as a large database buffer cache.

Paging space is allocated for shared memory regions just as it would for the process private segment (paging space is used as soon as the pages are touched if deferred page space allocation policy is off).

Extended Shared Memory (EXTSHM)

By default, each shared memory region (whatever its size), always consumes a 256 MB region of address space. AIX 4.2.1 and later implements Extended Shared Memory, which allows for more granular shared memory regions that can be in size of 1 byte up to 256 MB. However, the address space consumption will be rounded up to the next page (4096 byte) boundary. Extended Shared Memory essentially removes the limitation of only 11 shared memory regions.

This feature is available to processes that have the variable `EXTSHM` set to `ON` (`EXTSHM=ON`) in their process environment. There is no limit on the number of shared memory regions that a process can attach. File mapping is supported as before, but still consumes address space that is a multiple of 256 MB (segment size). Resizing a shared memory region is not supported in this mode. Kernel processes will still have the same behavior. Without this environment variable set, eleven 256 MB regions are available.

Extended Shared Memory has the following restrictions:

- I/O support is restricted in the same manner as for memory-mapped regions.
- Only `uphysio()` type of I/O is supported (no raw I/O).
- These shared memory regions cannot be used as I/O buffers where the unpinning of the buffer occurs in an interrupt handler. For example, these regions cannot be used for async I/O buffers.
- The segments cannot be pinned using the `plock()` subroutine because memory-mapped segments cannot be pinned with the `plock()` subroutine.

Chapter 8. Monitoring and Tuning Disk I/O Use

This chapter focuses on the performance of locally attached disk drives.

If you are not familiar with the operating system concepts of volume groups, logical and physical volumes, and logical and physical partitions, read Performance Overview of Fixed-Disk Storage Management.

File-system configuration has a large effect on overall system performance and is time-consuming to change after installation. Deciding on the number and types of hard disks, and the sizes and placements of paging spaces and logical volumes on those hard disks, is therefore a critical preinstallation process. For an extensive discussion of the considerations for preinstallation disk configuration planning, see Disk Preinstallation Guidelines.

The following sections are presented in this chapter:

- Monitoring Disk I/O
- Changing File System Attributes that Affect Performance
- Changing Logical Volume Attributes That Affect Performance
- Physical Volume Considerations
- Volume Group Recommendations
- Reorganizing Logical Volumes
- Reorganizing File Systems
- Reorganizing JFS Log and Log Logical Volumes
- Tuning with vmtune
- Using Disk-I/O Pacing
- Tuning Logical Volume Striping
- Tuning Asynchronous Disk I/O
- Tuning Direct I/O
- Using Raw Disk I/O
- Using sync/fsync Calls
- Setting SCSI-Adapter and Disk-Device Queue Limits
- Expanding the Configuration
- Using RAID
- Using SSA
- Using Fast Write Cache

Monitoring Disk I/O

When you are monitoring disk I/O, use the following to determine your course of action:

- Find the most active files, file systems, and logical volumes:
 - Can "hot" file systems be better located on the physical drive or be spread across multiple physical drives? (**lslv**, **iostat**, **filemon**)
 - Are "hot" files local or remote? (**filemon**)
 - Does paging space dominate disk utilization? (**vmstat**, **filemon**)
 - Is there enough memory to cache the file pages being used by running processes? (**vmstat**, **svmon**, **vmtune**)
 - Does the application perform a lot of synchronous (non-cached) file I/O?
- Determine file fragmentation:
 - Are "hot" files heavily fragmented? (**fileplace**)

- Find the physical volume with the highest utilization:
 - Is the type of drive or I/O adapter causing a bottleneck? (**iostat**, **filemon**)

Building a Pre-Tuning Baseline

Before you make significant changes in your disk configuration or tuning parameters, it is a good idea to build a baseline of measurements that record the current configuration and performance.

Wait I/O Time Reporting

AIX 4.3.3 and later contain enhancements to the method used to compute the percentage of CPU time spent waiting on disk I/O (wio time). The method used in AIX 4.3.2 and earlier versions of the operating system can, under certain circumstances, give an inflated view of wio time on SMPs. The wio time is reported by the commands **sar** (%wio), **vmstat** (wa) and **iostat** (% iowait).

Another change is that the wa column details the percentage of time the CPU was *idle* with pending disk I/O to not only local, but also NFS-mounted disks.

Method Used in AIX 4.3.2 and Earlier

At each clock interrupt on each processor (100 times a second per processor), a determination is made as to which of the four categories (usr/sys/wio/idle) to place the last 10 ms of time. If the CPU was busy in usr mode at the time of the clock interrupt, then usr gets the clock tick added into its category. If the CPU was busy in kernel mode at the time of the clock interrupt, then the sys category gets the tick. If the CPU was not busy, a check is made to see if any I/O to disk is in progress. If any disk I/O is in progress, the wio category is incremented. If no disk I/O is in progress and the CPU is not busy, the idle category gets the tick.

The inflated view of wio time results from all idle CPUs being categorized as wio regardless of the number of threads waiting on I/O. For example, systems with just one thread doing I/O could report over 90 percent wio time regardless of the number of CPUs it has.

Method Used in AIX 4.3.3 and Later

The change in AIX 4.3.3 is to only mark an idle CPU as wio if an outstanding I/O was started on that CPU. This method can report much lower wio times when just a few threads are doing I/O and the system is otherwise idle. For example, a system with four CPUs and one thread doing I/O will report a maximum of 25 percent wio time. A system with 12 CPUs and one thread doing I/O will report a maximum of 8.3 percent wio time.

Also, NFS now goes through the buffer cache, and waits in those routines are accounted for in the wa statistics.

Assessing Disk Performance with the iostat Command

Begin the assessment by running the **iostat** command with an interval parameter during your system's peak workload period or while running a critical application for which you need to minimize I/O delays. The following shell script runs the **iostat** command in the background while a copy of a large file runs in the foreground so that there is some I/O to measure:

```
# iostat 5 3 >io.out &
# cp big1 /dev/null
```

This example leaves the following three reports in the **io.out** file:

```
tty:      tin          tout  avg-cpu:  % user   % sys    % idle   % iowait
          0.0          1.3      0.2     0.6     98.9     0.3

Disks:    % tm_act   Kbps    tps     Kb_read  Kb_wrtn
hdisk0    0.0         0.3     0.0     29753    48076
hdisk1    0.1         0.1     0.0     11971    26460
hdisk2    0.2         0.8     0.1     91200    108355
cd0       0.0         0.0     0.0      0         0
```

```

tty:      tin          tout  avg-cpu: % user   % sys   % idle   % iowait
          0.8          0.8           0.6    9.7    50.2    39.5

```

```

Disks:    % tm_act    Kbps    tps    Kb_read  Kb_wrtn
hdisk0    47.0       674.6   21.8   3376     24
hdisk1    1.2        2.4     0.6    0        12
hdisk2    4.0        7.9     1.8    8        32
cd0       0.0        0.0     0.0    0        0

```

```

tty:      tin          tout  avg-cpu: % user   % sys   % idle   % iowait
          2.0          2.0           0.2    1.8    93.4    4.6

```

```

Disks:    % tm_act    Kbps    tps    Kb_read  Kb_wrtn
hdisk0    0.0        0.0     0.0    0        0
hdisk1    0.0        0.0     0.0    0        0
hdisk2    4.8       12.8     3.2    64       0
cd0       0.0        0.0     0.0    0        0

```

The first report is the summary since the last reboot and shows the overall balance (or, in this case, imbalance) in the I/O to each of the hard disks. hdisk1 is almost idle and hdisk2 receives about 63 percent of the total I/O (from Kb_read and Kb_wrtn).

Note: The system maintains a history of disk activity. If the history is disabled (**smitty chgsys -> Continuously maintain DISK I/O history [false]**), the following message displays when you run the **iotstat** command:

```
Disk history since boot not available.
```

The interval disk I/O statistics are unaffected by this.

The second report shows the 5-second interval during which **cp** ran. Examine this information carefully. The elapsed time for this **cp** was about 2.6 seconds. Thus, 2.5 seconds of high I/O dependency are being averaged with 2.5 seconds of idle time to yield the 39.5 percent % iowait reported. A shorter interval would have given a more accurate characterization of the command itself, but this example demonstrates what you must consider when you are looking at reports that show average activity across intervals.

TTY Report

The two columns of TTY information (tin and tout) in the **iotstat** output show the number of characters read and written by all TTY devices. This includes both real and pseudo TTY devices. Real TTY devices are those connected to an asynchronous port. Some pseudo TTY devices are shells, **telnet** sessions, and **aixterm** windows.

Because the processing of input and output characters consumes CPU resources, look for a correlation between increased TTY activity and CPU utilization. If such a relationship exists, evaluate ways to improve the performance of the TTY subsystem. Steps that could be taken include changing the application program, modifying TTY port parameters during file transfer, or perhaps upgrading to a faster or more efficient asynchronous communications adapter.

In Shell Script fastport.sh for Fast File Transfers, you can find the **fastport.sh** script, which is intended to condition a TTY port for fast file transfers in raw mode; for example, when a FAX machine is to be connected. Using the script might improve CPU performance by a factor of 3 at 38400 baud.

CPU Report

The CPU statistics columns (% user, % sys, % idle, and % iowait) provide a breakdown of CPU usage. This information is also reported in the **vmstat** command output in the columns labeled us, sy, id, and wa. For a detailed explanation for the values, see The vmstat Command. Also note the change made to % iowait described in Wait I/O Time Reporting.

On systems running one application, high I/O wait percentage might be related to the workload. On systems with many processes, some will be running while others wait for I/O. In this case, the % iowait can be small or zero because running processes "hide" some wait time. Although % iowait is low, a bottleneck can still limit application performance.

If the **iotstat** command indicates that a CPU-bound situation does not exist, and % iowait time is greater than 20 percent, you might have an I/O or disk-bound situation. This situation could be caused by excessive paging due to a lack of real memory. It could also be due to unbalanced disk load, fragmented data or usage patterns. For an unbalanced disk load, the same **iotstat** report provides the necessary information. But for information about file systems or logical volumes, which are logical resources, you must use tools such as the **filemon** or **fileplace** commands.

Drive Report

When you suspect a disk I/O performance problem, use the **iotstat** command. To avoid the information about the TTY and CPU statistics, use the **-d** option. In addition, the disk statistics can be limited to the important disks by specifying the disk names.

Remember that the first set of data represents all activity since system startup.

Disks: Shows the names of the physical volumes. They are either **hdisk** or **cd** followed by a number. If physical volume names are specified with the **iotstat** command, only those names specified are displayed.

% tm_act

Indicates the percentage of time that the physical disk was active (bandwidth utilization for the drive) or, in other words, the total time disk requests are outstanding. A drive is active during data transfer and command processing, such as seeking to a new location. The "disk active time" percentage is directly proportional to resource contention and inversely proportional to performance. As disk use increases, performance decreases and response time increases. In general, when the utilization exceeds 70 percent, processes are waiting longer than necessary for I/O to complete because most UNIX processes block (or sleep) while waiting for their I/O requests to complete. Look for busy versus idle drives. Moving data from busy to idle drives can help alleviate a disk bottleneck. Paging to and from disk will contribute to the I/O load.

Kbps Indicates the amount of data transferred (read or written) to the drive in KB per second. This is the sum of **Kb_read** plus **Kb_wrtn**, divided by the seconds in the reporting interval.

tps Indicates the number of transfers per second that were issued to the physical disk. A transfer is an I/O request through the device driver level to the physical disk. Multiple logical requests can be combined into a single I/O request to the disk. A transfer is of indeterminate size.

Kb_read

Reports the total data (in KB) read from the physical volume during the measured interval.

Kb_wrtn

Shows the amount of data (in KB) written to the physical volume during the measured interval.

Taken alone, there is no unacceptable value for any of the above fields because statistics are too closely related to application characteristics, system configuration, and type of physical disk drives and adapters. Therefore, when you are evaluating data, look for patterns and relationships. The most common relationship is between disk utilization (%tm_act) and data transfer rate (tps).

To draw any valid conclusions from this data, you have to understand the application's disk data access patterns such as sequential, random, or combination, as well as the type of physical disk drives and adapters on the system. For example, if an application reads/writes sequentially, you should expect a high disk transfer rate (Kbps) when you have a high disk busy rate (%tm_act). Columns **Kb_read** and **Kb_wrtn** can confirm an understanding of an application's read/write behavior. However, these columns provide no information on the data access patterns.

Generally you do not need to be concerned about a high disk busy rate (%tm_act) as long as the disk transfer rate (Kbps) is also high. However, if you get a high disk busy rate and a low disk transfer rate, you may have a fragmented logical volume, file system, or individual file.

Discussions of disk, logical volume and file system performance sometimes lead to the conclusion that the more drives you have on your system, the better the disk I/O performance. This is not always true because there is a limit to the amount of data that can be handled by a disk adapter. The disk adapter can also become a bottleneck. If all your disk drives are on one disk adapter, and your hot file systems are on separate physical volumes, you might benefit from using multiple disk adapters. Performance improvement will depend on the type of access.

To see if a particular adapter is saturated, use the **iostat** command and add up all the Kbps amounts for the disks attached to a particular disk adapter. For maximum aggregate performance, the total of the transfer rates (Kbps) must be below the disk adapter throughput rating. In most cases, use 70 percent of the throughput rate. In operating system versions later than 4.3.3 the **-a** or **-A** option will display this information.

Assessing Disk Performance with the vmstat Command

To prove that the system is I/O bound, it is better to use the **iostat** command. However, the **vmstat** command could point to that direction by looking at the wa column, as discussed in The vmstat Command. Other indicators for I/O bound are:

- The disk xfer part of the **vmstat** output

To display a statistic about the logical disks (a maximum of four disks is allowed), use the following command:

```
# vmstat hdisk0 hdisk1 1 8
kthr      memory          page                faults           cpu       disk xfer
-----  -
r  b   avm   fre  re  pi  po  fr  sr  cy  in  sy  cs  us  sy  id  wa  1  2  3  4
0  0  3456 27743  0  0  0  0  0  0 131 149 28  0  1 99  0  0  0  0
0  0  3456 27743  0  0  0  0  0  0 131  77 30  0  1 99  0  0  0  0
1  0  3498 27152  0  0  0  0  0  0 153 1088 35  1 10 87  2  0 11
0  1  3499 26543  0  0  0  0  0  0 199 1530 38  1 19  0 80  0 59
0  1  3499 25406  0  0  0  0  0  0 187 2472 38  2 26  0 72  0 53
0  0  3456 24329  0  0  0  0  0  0 178 1301 37  2 12 20 66  0 42
0  0  3456 24329  0  0  0  0  0  0 124  58 19  0  0 99  0  0  0
0  0  3456 24329  0  0  0  0  0  0 123  58 23  0  0 99  0  0  0
```

The disk xfer part provides the number of transfers per second to the specified physical volumes that occurred in the sample interval. One to four physical volume names can be specified. Transfer statistics are given for each specified drive in the order specified. This count represents requests to the physical device. It does not imply an amount of data that was read or written. Several logical requests can be combined into one physical request.

- The in column of the **vmstat** output

This column shows the number of hardware or device interrupts (per second) observed over the measurement interval. Examples of interrupts are disk request completions and the 10 millisecond clock interrupt. Since the latter occurs 100 times per second, the in field is always greater than 100. But the **vmstat** command also provides a more detailed output about the system interrupts.

- The **vmstat -i** output

The **-i** parameter displays the number of interrupts taken by each device since system startup. But, by adding the interval and, optionally, the count parameter, the statistic since startup is only displayed in the first stanza; every trailing stanza is a statistic about the scanned interval.

```
# vmstat -i 1 2
priority level  type  count module(handler)
0              0  hardware  0 i_misc_pwr(a868c)
0              1  hardware  0 i_scu(a8680)
0              2  hardware  0 i_epow(954e0)
```

```

0      2  hardware      0 /etc/drivers/ascsiddpin(189acd4)
1      2  hardware    194 /etc/drivers/rsdd(1941354)
3     10  hardware 10589024 /etc/drivers/mpsdd(1977a88)
3     14  hardware 101947 /etc/drivers/ascsiddpin(189ab8c)
5     62  hardware 61336129 clock(952c4)
10    63  hardware 13769 i_softoff(9527c)
priority level  type  count module(handler)
0      0  hardware      0 i_misc_pwr(a868c)
0      1  hardware      0 i_scu(a8680)
0      2  hardware      0 i_epow(954e0)
0      2  hardware      0 /etc/drivers/ascsiddpin(189acd4)
1      2  hardware      0 /etc/drivers/rsdd(1941354)
3     10  hardware     25 /etc/drivers/mpsdd(1977a88)
3     14  hardware      0 /etc/drivers/ascsiddpin(189ab8c)
5     62  hardware    105 clock(952c4)
10    63  hardware      0 i_softoff(9527c)

```

Note: The output will differ from system to system, depending on hardware and software configurations (for example, the clock interrupts may not be displayed in the **vmstat -i** output although they will be accounted for under the **in** column in the normal **vmstat** output). Check for high numbers in the count column and investigate why this module has to execute so many interrupts.

Assessing Disk Performance with the sar Command

The **sar** command is a standard UNIX command used to gather statistical data about the system. With its numerous options, the **sar** command provides queuing, paging, TTY, and many other statistics. With AIX 4.3.3, the **sar -d** option generates real-time disk I/O statistics.

```
# sar -d 3 3
```

```

AIX konark 3 4 0002506F4C00 08/26/99

12:09:50 device %busy avque r+w/s blks/s await avserv

Average hdisk0 0 0.0 0 3 0.0 0.0
          hdisk1 0 0.0 0 1 0.0 0.0
          cd0 0 0.0 0 0 0.0 0.0

```

The fields listed by the **sar -d** command are as follows:

%busy

Portion of time device was busy servicing a transfer request. This is the same as the **%tm_act** column in the **iostat** command report.

avque Average number of requests outstanding during that time. This number is a good indicator if an I/O bottleneck exists.

r+w/s Number of read/write transfers from or to device. This is the same as **tps** in the **iostat** command report.

blks/s Number of bytes transferred in 512-byte units

await

Average number of transactions waiting for service (queue length). Average time (in milliseconds) that transfer requests waited idly on queue for the device. This number is currently not reported and shows 0.0 by default.

avserv

Number of milliseconds per average seek. Average time (in milliseconds) to service each transfer request (includes seek, rotational latency, and data transfer times) for the device. This number is currently not reported and shows 0.0 by default.

Assessing Logical Volume Fragmentation with the lslv Command

The **lslv** command shows, among other information, the logical volume fragmentation. To check logical volume fragmentation, use the command **lslv -l lvname**, as follows:

```
# lslv -l hd2
hd2:/usr
PV          COPIES      IN BAND      DISTRIBUTION
hdisk0      114:000:000    22%          000:042:026:000:046
```

The output of COPIES shows the logical volume hd2 has only one copy. The IN BAND shows how well the intrapolicy, an attribute of logical volumes, is followed. The higher the percentage, the better the allocation efficiency. Each logical volume has its own intrapolicy. If the operating system cannot meet this requirement, it chooses the best way to meet the requirements. In our example, there are a total of 114 logical partitions (LP); 42 LPs are located on middle, 26 LPs on center, and 46 LPs on inner-edge. Since the logical volume intrapolicy is center, the in-band is 22 percent (26 / (42+26+46)). The DISTRIBUTION shows how the physical partitions are placed in each part of the intrapolicy; that is:

```
edge : middle : center : inner-middle : inner-edge
```

See Position on Physical Volume for additional information about physical partitions placement.

Assessing Physical Placement of Data with the lslv Command

If the workload shows a significant degree of I/O dependency, you can investigate the physical placement of the files on the disk to determine if reorganization at some level would yield an improvement. To see the placement of the partitions of logical volume hd11 within physical volume hdisk0, use the following:

```
# lslv -p hdisk0 hd11
hdisk0:hd11:/home/op
USED  USED  USED  USED  USED  USED  USED  USED  USED  USED  1-10
USED  USED  USED  USED  USED  USED  USED  USED  USED  USED  11-17

USED  USED  USED  USED  USED  USED  USED  USED  USED  USED  18-27
USED  USED  USED  USED  USED  USED  USED  USED  USED  USED  28-34

USED  USED  USED  USED  USED  USED  USED  USED  USED  USED  35-44
USED  USED  USED  USED  USED  USED  USED  USED  USED  USED  45-50

USED  USED  USED  USED  USED  USED  USED  USED  USED  USED  51-60
0052 0053 0054 0055 0056 0057 0058  USED  USED  USED  61-67

0059 0060 0061 0062 0063 0064 0065 0066 0067 0068  68-77
0069 0070 0071 0072 0073 0074 0075  USED  USED  USED  78-84
```

Look for the rest of hd11 on hdisk1 with the following:

```
# lslv -p hdisk1 hd11
hdisk1:hd11:/home/op
0035 0036 0037 0038 0039 0040 0041 0042 0043 0044  1-10
0045 0046 0047 0048 0049 0050 0051  USED  USED  USED  11-17

USED  USED  USED  USED  USED  USED  USED  USED  USED  USED  18-27
USED  USED  USED  USED  USED  USED  USED  USED  USED  USED  28-34
```

```

USED  USED  USED  USED  USED  USED  USED  USED  USED  USED  35-44
USED  USED  USED  USED  USED  USED
0001  0002  0003  0004  0005  0006  0007  0008  0009  0010  51-60
0011  0012  0013  0014  0015  0016  0017
0018  0019  0020  0021  0022  0023  0024  0025  0026  0027  68-77
0028  0029  0030  0031  0032  0033  0034

```

From top to bottom, five blocks represent edge, middle, center, inner-middle, and inner-edge, respectively.

- A USED indicates that the physical partition at this location is used by a logical volume other than the one specified. A number indicates the logical partition number of the logical volume specified with the **lslv -p** command.
- A FREE indicates that this physical partition is not used by any logical volume. Logical volume fragmentation occurs if logical partitions are not contiguous across the disk.
- A STALE physical partition is a physical partition that contains data you cannot use. You can also see the STALE physical partitions with the **lspv -m** command. Physical partitions marked as STALE must be updated to contain the same information as valid physical partitions. This process, called resynchronization with the **syncvg** command, can be done at vary-on time, or can be started anytime the system is running. Until the STALE partitions have been rewritten with valid data, they are not used to satisfy read requests, nor are they written to on write requests.

In the previous example, logical volume hd11 is fragmented within physical volume hdisk1, with its first logical partitions in the inner-middle and inner regions of hdisk1, while logical partitions 35-51 are in the outer region. A workload that accessed hd11 randomly would experience unnecessary I/O wait time as longer seeks might be needed on logical volume hd11. These reports also indicate that there are no free physical partitions in either hdisk0 or hdisk1.

Assessing File Placement with the fileplace Command

To see how the file copied earlier, **big1**, is stored on the disk, we can use the **fileplace** command. The **fileplace** command displays the placement of a file's blocks within a logical volume or within one or more physical volumes.

To determine whether the **fileplace** command is installed and available, run the following command:

```
# lslpp -lI perfagent.tools
```

Use the following command:

```
# fileplace -pv big1
```

```
File: big1 Size: 3554273 bytes Vol: /dev/hd10
Blk Size: 4096 Frag Size: 4096 Nfrags: 868 Compress: no
Inode: 19 Mode: -rwxr-xr-x Owner: hoetzel Group: system
```

Physical Addresses (mirror copy 1)	Logical Fragment
0001584-0001591 hdisk0 8 frags 32768 Bytes, 0.9%	0001040-0001047
0001624-0001671 hdisk0 48 frags 196608 Bytes, 5.5%	0001080-0001127
0001728-0002539 hdisk0 812 frags 3325952 Bytes, 93.5%	0001184-0001995

```
868 frags over space of 956 frags: space efficiency = 90.8%
3 fragments out of 868 possible: sequentiality = 99.8%
```

This example shows that there is very little fragmentation within the file, and those are small gaps. We can therefore infer that the disk arrangement of **big1** is not significantly affecting its sequential read-time. Further, given that a (recently created) 3.5 MB file encounters this little fragmentation, it appears that the file system in general has not become particularly fragmented.

Occasionally, portions of a file may not be mapped to any blocks in the volume. These areas are implicitly filled with zeroes by the file system. These areas show as unallocated logical blocks. A file that has these holes will show the file size to be a larger number of bytes than it actually occupies (that is, the **ls -l** command will show a large size, whereas the **du** command will show a smaller size or the number of blocks the file really occupies on disk).

The **fileplace** command reads the file's list of blocks from the logical volume. If the file is new, the information may not be on disk yet. Use the **sync** command to flush the information. Also, the **fileplace** command will not display NFS remote files (unless the command runs on the server).

Note: If a file has been created by seeking to various locations and writing widely dispersed records, only the pages that contain records will take up space on disk and appear on a **fileplace** report. The file system does not fill in the intervening pages automatically when the file is created. However, if such a file is read sequentially (by the **cp** or **tar** commands, for example) the space between records is read as binary zeroes. Thus, the output of such a **cp** command can be much larger than the input file, although the data is the same.

Space Efficiency and Sequentiality

Higher space efficiency means files are less fragmented and probably provide better sequential file access. A higher sequentiality indicates that the files are more contiguously allocated, and this will probably be better for sequential file access.

Space efficiency =

Total number of fragments used for file storage /
(Largest fragment physical address -
Smallest fragment physical address + 1)

Sequentiality =

(Total number of fragments -
Number of grouped fragments + 1) /
Total number of fragments

If you find that your sequentiality or space efficiency values become low, you can use the **reorgvg** command to improve logical volume utilization and efficiency (see Reorganizing Logical Volumes). To improve file system utilization and efficiency, see Reorganizing File Systems.

In this example, the Largest fragment physical address - Smallest fragment physical address + 1 is: 0002539 - 0001584 + 1 = 956 fragments; total used fragments is: 8 + 48 + 812 = 868; the space efficiency is 868 / 956 (90.8 percent); the sequentiality is (868 - 3 + 1) / 868 = 99.8 percent.

Because the total number of fragments used for file storage does not include the indirect blocks location, but the physical address does, the space efficiency can never be 100 percent for files larger than 32 KB, even if the file is located on contiguous fragments.

Assessing Paging Space I/O with the vmstat Command

I/O to and from paging spaces is random, mostly one page at a time. The **vmstat** reports indicate the amount of paging-space I/O taking place. Both of the following examples show the paging activity that occurs during a C compilation in a machine that has been artificially shrunk using the **rmss** command. The **pi** and **po** (paging-space page-ins and paging-space page-outs) columns show the amount of paging-space I/O (in terms of 4096-byte pages) during each 5-second interval. The first report (summary since system reboot) has been removed. Notice that the paging activity occurs in bursts.

```
# vmstat 5 8
kthr      memory          page          faults          cpu
-----
r  b   avm    fre  re  pi  po  fr  sr  cy  in  sy  cs  us  sy  id  wa
0  1 72379  434   0   0   0   0   2   0 376 192 478   9   3 87   1
0  1 72379  391   0   8   0   0   0   0 631 2967 775  10   1 83   6
0  1 72379  391   0   0   0   0   0   0 625 2672 790   5   3 92   0
```

```

0 1 72379 175 0 7 0 0 0 0 721 3215 868 8 4 72 16
2 1 71384 877 0 12 13 44 150 0 662 3049 853 7 12 40 41
0 2 71929 127 0 35 30 182 666 0 709 2838 977 15 13 0 71
0 1 71938 122 0 0 8 32 122 0 608 3332 787 10 4 75 11
0 1 71938 122 0 0 0 3 12 0 611 2834 733 5 3 75 17

```

The following "before and after" **vmstat -s** reports show the accumulation of paging activity. Remember that it is the paging space page ins and paging space page outs that represent true paging-space I/O. The (unqualified) page ins and page outs report total I/O, that is both paging-space I/O and the ordinary file I/O, performed by the paging mechanism. The reports have been edited to remove lines that are irrelevant to this discussion.

# vmstat -s # before	# vmstat -s # after
6602 page ins	7022 page ins
3948 page outs	4146 page outs
544 paging space page ins	689 paging space page ins
1923 paging space page outs	2032 paging space page outs
0 total reclaims	0 total reclaims

The fact that more paging-space page-ins than page-outs occurred during the compilation suggests that we had shrunk the system to the point that thrashing begins. Some pages were being repaged because their frames were stolen before their use was complete.

Assessing Overall Disk I/O with the vmstat Command

The technique just discussed can also be used to assess the disk I/O load generated by a program. If the system is otherwise idle, the following sequence:

```

# vmstat -s >statout
# testpgm
# sync
# vmstat -s >> statout
# egrep "ins|outs" statout

```

yields a before and after picture of the cumulative disk activity counts, such as:

```

5698 page ins
5012 page outs
  0 paging space page ins
 32 paging space page outs
6671 page ins
5268 page outs
  8 paging space page ins
 25 paging space page outs

```

During the period when this command (a large C compile) was running, the system read a total of 981 pages (8 from paging space) and wrote a total of 449 pages (193 to paging space).

Detailed I/O Analysis with the filemon Command

The **filemon** command uses the trace facility to obtain a detailed picture of I/O activity during a time interval on the various layers of file system utilization, including the logical file system, virtual memory segments, LVM, and physical disk layers. Data can be collected on all the layers, or layers can be specified with the **-O** layer option. The default is to collect data on the VM, LVM, and physical layers. Both summary and detailed reports are generated. Since it uses the trace facility, the **filemon** command can be run only by the root user or by a member of the system group.

To determine whether the **filemon** command is installed and available, run the following command:

```
# ls1pp -lI perfaqent.tools
```

Tracing is started by the **filemon** command, optionally suspended with the **trcoff** subcommand and resumed with the **trcon** subcommand, and terminated with the **trcstop** subcommand (you may want to issue the command **nice -n -20 trcstop** to stop the **filemon** command since the **filemon** command is currently running at priority 40). As soon as tracing is terminated, the **filemon** command writes its report to stdout.

Note: Only data for those files opened after the **filemon** command was started will be collected, unless you specify the **-u** flag.

The **filemon** command can read the I/O trace data from a specified file, instead of from the real-time trace process. In this case, the **filemon** report summarizes the I/O activity for the system and period represented by the trace file. This offline processing method is useful when it is necessary to postprocess a trace file from a remote machine or perform the trace data collection at one time and postprocess it at another time.

The **trcrpt -r** command must be executed on the trace logfile and redirected to another file, as follows:

```
# gennames > gennames.out
# trcrpt -r trace.out > trace.rpt
```

At this point an adjusted trace logfile is fed into the **filemon** command to report on I/O activity captured by a previously recorded trace session as follows:

```
# filemon -i trace.rpt -n gennames.out | pg
```

In this example, the **filemon** command reads file system trace events from the input file **trace.rpt**. Because the trace data is already captured on a file, the **filemon** command does not put itself in the background to allow application programs to be run. After the entire file is read, an I/O activity report for the virtual memory, logical volume, and physical volume levels is displayed on standard output (which, in this example, is piped to the **pg** command).

If the **trace** command was run with the **-C all** flag, then run the **trcrpt** command also with the **-C all** flag (see Formatting a Report from trace -C Output).

The following sequence of commands gives an example of the **filemon** command usage:

```
# filemon -o fm.out -0 all; cp /smit.log /dev/null ; trcstop
```

The report produced by this sequence, in an otherwise-idle system, is as follows:

```
Thu Aug 19 11:30:49 1999
System: AIX texmex Node: 4 Machine: 000691854C00
```

```
0.369 secs in measured interval
Cpu utilization: 9.0%
```

```

Using the **filemon** command in systems with real workloads would result in much larger reports and might require more trace buffer space. Space and CPU time consumption for the **filemon** command can degrade system performance to some extent. Use a nonproduction system to experiment with the **filemon** command before starting it in a production environment. Also, use offline processing and on systems with many CPUs use the **-C all** flag with the **trace** command.

Note: Although the **filemon** command reports average, minimum, maximum, and standard deviation in its detailed-statistics sections, the results should not be used to develop confidence intervals or other formal statistical inferences. In general, the distribution of data points is neither random nor symmetrical.

Global Reports of the filemon Command

The global reports list the most active files, segments, logical volumes, and physical volumes during the measured interval. They are shown at the beginning of the **filemon** report. By default, the logical file and virtual memory reports are limited to the 20 most active files and segments, respectively, as measured by the total amount of data transferred. If the **-v** flag has been specified, activity for all files and segments is reported. All information in the reports is listed from top to bottom as most active to least active.

Most Active Files:

#MBs Total number of MBs transferred over measured interval for this file. The rows are sorted by this field in decreasing order.

#opns Number of opens for files during measurement period.

#rds Number of read calls to file.

#wrs Number of write calls to file.

file File name (full path name is in detailed report).

volume:inode

The logical volume that the file resides in and the i-node number of the file in the associated file system. This field can be used to associate a file with its corresponding persistent segment shown in the detailed VM segment reports. This field may be blank for temporary files created and deleted during execution.

The most active files are **smit.log** on logical volume hd4 and file **null**. The application utilizes the terminfo database for screen management; so the **ksh.cat** and **cmdtrace.cat** are also busy. Anytime the shell needs to post a message to the screen, it uses the catalogs for the source of the data.

To identify unknown files, you can translate the logical volume name, **/dev/hd1**, to the mount point of the file system, **/home**, and use the **find** or the **ncheck** command:

```
# find / -inum 858 -print
/smit.log
```

or

```
# ncheck -i 858 /
/:
858    /smit.log
```

Most Active Segments:

#MBs Total number of MBs transferred over measured interval for this segment. The rows are sorted by this field in decreasing order.

#rpgs Number of 4-KB pages read into segment from disk.

#wpgs

Number of 4-KB pages written from segment to disk (page out).

#segid

VMM ID of memory segment.

segtype

Type of segment: working segment, persistent segment (local file), client segment (remote file), page table segment, system segment, or special persistent segments containing file system data (log, root directory, .inode, .inodemap, .inodex, .inodexmap, .indirect, .diskmap).

volume:inode

For persistent segments, name of logical volume that contains the associated file and the file's i-node number. This field can be used to associate a persistent segment with its corresponding file, shown in the Detailed File Stats reports. This field is blank for nonpersistent segments.

If the command is still active, the virtual memory analysis tool **svmon** can be used to display more information about a segment, given its segment ID (*segid*), as follows: **svmon -D segid**. See The svmon Command for a detailed discussion.

In our example, the segtype ??? means that the system cannot identify the segment type, and you must use the **svmon** command to get more information.

Most Active Logical Volumes:

util Utilization of logical volume.

#rblk Number of 512-byte blocks read from logical volume.

#wblk Number of 512-byte blocks written to logical volume.

KB/s Average transfer data rate in KB per second.

volume

Logical volume name.

description

Either the file system mount point or the logical volume type (paging, jfslog, boot, or sysdump). For example, the logical volume **/dev/hd2** is **/usr**; **/dev/hd6** is paging, and **/dev/hd8** is jfslog. There may also be the word *compressed*. This means all data is compressed automatically using Lempel-Zev (LZ) compression before being written to disk, and all data is uncompressed automatically when read from disk (see Compression for details).

The utilization is presented in percentage, 0.06 indicates 6 percent busy during measured interval.

Most Active Physical Volumes:

util Utilization of physical volume.

Note: Logical volume I/O requests start before and end after physical volume I/O requests. Total logical volume utilization will appear therefore to be higher than total physical volume utilization.

#rblk Number of 512-byte blocks read from physical volume.

#wblk Number of 512-byte blocks written to physical volume.

KB/s Average transfer data rate in KB per second.

volume

Physical volume name.

description

Simple description of the physical volume type, for example, SCSI Multimedia CD-ROM Drive or 16 Bit SCSI Disk Drive.

The utilization is presented in percentage, 0.10 indicates 10 percent busy during measured interval.

Detailed Reports of the filemon Command

The detailed reports give additional information for the global reports. There is one entry for each reported file, segment, or volume in the detailed reports. The fields in each entry are described below for the four detailed reports. Some of the fields report a single value; others report statistics that characterize a distribution of many values. For example, response-time statistics are kept for all read or write requests

that were monitored. The average, minimum, and maximum response times are reported, as well as the standard deviation of the response times. The standard deviation is used to show how much the individual response times deviated from the average. Approximately two-thirds of the sampled response times are between average minus standard deviation (avg - sdev) and average plus standard deviation (avg + sdev). If the distribution of response times is scattered over a large range, the standard deviation will be large compared to the average response time.

Detailed File Stats: Detailed file statistics are provided for each file listed in the Most Active Files report. These stanzas can be used to determine what access has been made to the file. In addition to the number of total bytes transferred, opens, reads, writes, and lseeks, the user can also determine the read/write size and times.

FILE Name of the file. The full path name is given, if possible.

volume

Name of the logical volume/file system containing the file.

inode I-node number for the file within its file system.

opens Number of times the file was opened while monitored.

total bytes xfrd

Total number of bytes read/written from/to the file.

reads Number of read calls against the file.

read sizes (bytes)

Read transfer-size statistics (avg/min/max/sdev), in bytes.

read times (msec)

Read response-time statistics (avg/min/max/sdev), in milliseconds.

writes Number of write calls against the file.

write sizes (bytes)

Write transfer-size statistics.

write times (msec)

Write response-time statistics.

lseeks

Number of **lseek()** subroutine calls.

The read sizes and write sizes will give you an idea of how efficiently your application is reading and writing information. Use a multiple of 4 KB pages for best results.

Detailed VM Segment Stats: Each element listed in the Most Active Segments report has a corresponding stanza that shows detailed information about real I/O to and from memory.

SEGMENT

Internal operating system's segment ID.

segtype

Type of segment contents.

segment flags

Various segment attributes.

volume

For persistent segments, the name of the logical volume containing the corresponding file.

inode For persistent segments, the i-node number for the corresponding file.

reads Number of 4096-byte pages read into the segment (that is, paged in).

read times (msec)

Read response-time statistics (avg/min/max/sdev), in milliseconds.

read sequences

Number of read sequences. A sequence is a string of pages that are read (paged in) consecutively. The number of read sequences is an indicator of the amount of sequential access.

read seq. lengths

Statistics describing the lengths of the read sequences, in pages.

writes Number of pages written from the segment to disk (that is, paged out).

write times (msec)

Write response-time statistics.

write sequences

Number of write sequences. A sequence is a string of pages that are written (paged out) consecutively.

write seq. lengths

Statistics describing the lengths of the write sequences, in pages.

By examining the reads and read-sequence counts, you can determine if the access is sequential or random. For example, if the read-sequence count approaches the reads count, the file access is more random. On the other hand, if the read-sequence count is significantly smaller than the read count and the read-sequence length is a high value, the file access is more sequential. The same logic applies for the writes and write sequence.

Detailed Logical/Physical Volume Stats: Each element listed in the Most Active Logical Volumes / Most Active Physical Volumes reports will have a corresponding stanza that shows detailed information about the logical/physical volume. In addition to the number of reads and writes, the user can also determine read and write times and sizes, as well as the initial and average seek distances for the logical / physical volume.

VOLUME

Name of the volume.

description

Description of the volume. (Describes contents, if dealing with a logical volume; describes type, if dealing with a physical volume.)

reads Number of read requests made against the volume.

read sizes (blks)

Read transfer-size statistics (avg/min/max/sdev), in units of 512-byte blocks.

read times (msec)

Read response-time statistics (avg/min/max/sdev), in milliseconds.

read sequences

Number of read sequences. A sequence is a string of 512-byte blocks that are read consecutively. It indicates the amount of sequential access.

read seq. lengths

Statistics describing the lengths of the read sequences, in blocks.

writes Number of write requests made against the volume.

write sizes (blks)

Write transfer-size statistics.

write times (msec)

Write-response time statistics.

write sequences

Number of write sequences. A sequence is a string of 512-byte blocks that are written consecutively.

write seq. lengths

Statistics describing the lengths of the write sequences, in blocks.

seeks Number of seeks that preceded a read or write request; also expressed as a percentage of the total reads and writes that required seeks.

seek dist (blks)

Seek-distance statistics in units of 512-byte blocks. In addition to the usual statistics (avg/min/max/sdev), the distance of the initial seek operation (assuming block 0 was the starting position) is reported separately. This seek distance is sometimes very large; it is reported separately to avoid skewing the other statistics.

seek dist (cyls)

(Physical volume only) Seek-distance statistics in units of disk cylinders.

time to next req

Statistics (avg/min/max/sdev) describing the length of time, in milliseconds, between consecutive read or write requests to the volume. This column indicates the rate at which the volume is being accessed.

throughput

Total volume throughput in KB per second.

utilization

Fraction of time the volume was busy. The entries in this report are sorted by this field in decreasing order.

A long seek time can increase I/O response time and result in decreased application performance. By examining the reads and read sequence counts, you can determine if the access is sequential or random. The same logic applies to the writes and write sequence.

Guidelines for Using the filemon Command

Following are some guidelines for using the **filemon** command:

- The **/etc/inittab** file is always very active. Daemons specified in **/etc/inittab** are checked regularly to determine whether they are required to be respawned.
- The **/etc/passwd** file is also always very active. Because files and directories access permissions are checked.
- A long seek time increases I/O response time and decreases performance.
- If the majority of the reads and writes require seeks, you might have fragmented files and overly active file systems on the same physical disk. However, for online transaction processing (OLTP) or database systems this behavior might be normal.
- If the number of reads and writes approaches the number of sequences, physical disk access is more random than sequential. Sequences are strings of pages that are read (paged in) or written (paged out) consecutively. The seq. lengths is the length, in pages, of the sequences. A random file access can also involve many seeks. In this case, you cannot distinguish from the **filemon** output if the file access is random or if the file is fragmented. Use the **fileplace** command to investigate further.
- Remote files are listed in the volume:inode column with the remote system name.

Because the **filemon** command can potentially consume some CPU power, use this tool with discretion, and analyze the system performance while taking into consideration the overhead involved in running the tool. Tests have shown that in a CPU-saturated environment:

- With little I/O, the **filemon** command slowed a large compile by about one percent.
- With a high disk-output rate, the **filemon** command slowed the writing program by about five percent.

Summary for Monitoring Disk I/O

In general, a high % `iowait` indicates that the system has an application problem, a memory shortage, or an inefficient I/O subsystem configuration. For example, the application problem might be due to requesting a lot of I/O, but not doing much with the data. Understanding the I/O bottleneck and improving the efficiency of the I/O subsystem is the key in solving this bottleneck. Disk sensitivity can come in a number of forms, with different resolutions. Some typical solutions might include:

- Limiting number of active logical volumes and file systems placed on a particular physical disk. The idea is to balance file I/O evenly across all physical disk drives.
- Spreading a logical volume across multiple physical disks. This is particularly useful when a number of different files are being accessed.
- Creating multiple Journaled File Systems (JFS) logs for a volume group and assigning them to specific file systems (preferably on fast write cache devices). This is beneficial for applications that create, delete, or modify a large number of files, particularly temporary files.
- If the `iostat` output indicates that your workload I/O activity is not evenly distributed among the system disk drives, and the utilization of one or more disk drives is often 70-80 percent or more, consider reorganizing file systems, such as backing up and restoring file systems to reduce fragmentation. Fragmentation causes the drive to seek excessively and can be a large portion of overall response time.
- If large, I/O-intensive background jobs are interfering with interactive response time, you may want to activate I/O pacing.
- If it appears that a small number of files are being read over and over again, consider whether additional real memory would allow those files to be buffered more effectively.
- If the workload's access pattern is predominantly random, you might consider adding disks and distributing the randomly accessed files across more drives.
- If the workload's access pattern is predominantly sequential and involves multiple disk drives, you might consider adding one or more disk adapters. It may also be appropriate to consider building a striped logical volume to accommodate large, performance-critical sequential files.
- Using fast write cache devices.
- Using synchronous writes.

Each technique is discussed later in this chapter.

Changing File System Attributes that Affect Performance

The longer a file system is used, the more fragmented it becomes. With the dynamic allocation of resources, file blocks become more and more scattered, logically contiguous files become fragmented, and logically contiguous logical volumes (LV) become fragmented.

When files are accessed from disk, the following take effect:

- Sequential access is no longer sequential
- Random access is slower
- Access time is dominated by longer seek time

However, once the file is in memory, these effects diminish. File system performance is also affected by physical considerations, such as:

- Types of disks and number of adapters
- Amount of memory for file buffering
- Amount of local versus remote file access
- Pattern and amount of file access by application

AIX Version 4 enables the ability to have file systems larger than 2 GB in size. In addition file system fragmentation allows for better space utilization by subdividing 4 K blocks. The number of bytes per i-node

(NBPI) is used to control how many i-nodes are created for a file system. Compression can be used for file systems with a fragment size less than 4 KB. Fragment size and compression affect performance and are discussed in the following.

File-System Fragment Size

The fragments feature in AIX Version 4 allows the space in a file system to be allocated in less than 4 KB chunks. When a file system is created, the system administrator can specify the size of the fragments in the file system. The allowable sizes are 512, 1024, 2048, and 4096 bytes (the default). Files smaller than a fragment are stored in a single fragment, conserving disk space, which is the primary objective.

Files smaller than 4096 bytes are stored in the minimum necessary number of contiguous fragments. Files whose size is between 4096 bytes and 32 KB (inclusive) are stored in one or more (4 KB) full blocks and in as many fragments as are required to hold the remainder. For example, a 5632-byte file would be allocated one 4 KB block, pointed to by the first pointer in the i-node. If the fragment size is 512, then eight fragments would be used for the first 4 KB block. The last 1.5 KB would use three fragments, pointed to by the second pointer in the i-node. For files greater than 32 KB, allocation is done in 4 KB blocks, and the i-node pointers point to these 4 KB blocks.

Whatever the fragment size, a full block is considered to be 4096 bytes. In a file system with a fragment size less than 4096 bytes, however, a need for a full block can be satisfied by any contiguous sequence of fragments totalling 4096 bytes. It need not begin on a multiple-of-4096-byte boundary.

The file system tries to allocate space for files in contiguous fragments by spreading the files themselves across the logical volume to minimize interfile allocation interference and fragmentation.

The primary performance hazard for file systems with small fragment sizes is space fragmentation. The existence of small files scattered across the logical volume can make it impossible to allocate contiguous or closely spaced blocks for a large file. Performance can suffer when accessing large files. Carried to an extreme, space fragmentation can make it impossible to allocate space for a file, even though there are many individual free fragments.

Another adverse effect on disk I/O activity is the number of I/O operations. For a file with a size of 4 KB stored in a single fragment of 4 KB, only one disk I/O operation would be required to either read or write the file. If the choice of the fragment size was 512 bytes, eight fragments would be allocated to this file, and for a read or write to complete, several additional disk I/O operations (disk seeks, data transfers, and allocation activity) would be required. Therefore, for file systems which use a fragment size of 4 KB, the number of disk I/O operations might be far less than for file systems which employ a smaller fragment size.

Part of a decision to create a small-fragment file system should be a policy for defragmenting the space in that file system with the **defragfs** command. This policy must also take into account the performance cost of running the **defragfs** command (see Defragmenting a File System).

Compression

If a file system is compressed, all data is compressed automatically using Lempel-Zev (LZ) compression before being written to disk, and all data is uncompressed automatically when read from disk. The LZ algorithm replaces subsequent occurrences of a given string with a pointer to the first occurrence. On an average, a 50 percent savings in disk space is realized.

In AIX Version 4, file system data is compressed at the level of an individual logical blocks. To compress data in large units (all the logical blocks of a file together, for example) would result in the loss of more available disk space. By individually compressing a file's logical blocks, random seeks and updates are carried out much more rapidly.

When a file is written into a file system for which compression is specified, the compression algorithm compresses the data 4096 bytes (a page) at a time, and the compressed data is then written in the minimum necessary number of contiguous fragments. Obviously, if the fragment size of the file system is 4 KB, there is no disk-space payback for the effort of compressing the data. Therefore, compression requires fragmentation to be used, with a fragment size smaller than 4096.

Although compression should result in conserving space overall, there are valid reasons for leaving some unused space in the file system:

- Because the degree to which each 4096-byte block of data will compress is not known in advance, the file system initially reserves a full block of space. The unneeded fragments are released after compression, but the conservative initial allocation policy may lead to premature "out of space" indications.
- Some free space is necessary to allow the **defragfs** command to operate.

In addition to increased disk I/O activity and free-space fragmentation problems, file systems using data compression have the following performance considerations:

- Degradation in file system usability arising as a direct result of the data compression/decompression activity. If the time to compress and decompress data is quite lengthy, it might not always be possible to use a compressed file system, particularly in a busy commercial environment where data needs to be available immediately.
- All logical blocks in a compressed file system, when modified for the first time, will be allocated 4096 bytes of disk space, and this space will subsequently be reallocated when the logical block is written to disk. Performance costs are associated with reallocation, which does not occur in noncompressed file systems.
- To perform data compression, approximately 50 CPU cycles per byte are required, and about 10 CPU cycles per byte for decompression. Data compression therefore places a load on the processor by increasing the number of processor cycles.
- The JFS compression kproc (jpsc) runs at a fixed priority of 30 so that while compression/decompression is occurring, the CPU that this kproc is running on may not be available to other processes unless they run at a better priority.

Changing Logical Volume Attributes That Affect Performance

Various factors have performance implications and can be controlled when creating a logical volume. These options appear as prompts for values on the **smitty mklv** screen.

Position on Physical Volume

The *Intra-Physical Volume Allocation Policy* specifies what strategy should be used for choosing physical partitions on a physical volume. The five general strategies are edge, inner-edge, middle, inner-middle, and center.

Figure 19. Intra-Physical Volume Allocation Policy. This figure illustrates storage position on a physical volume or disk. The disk is formatted into hundreds of tracks beginning at the outer edge of the disk and moving toward the center of the disk. Because of the way a disk is read (the tracks spinning under a movable read/write head), data that is written toward the center of the disk will have faster seek times than data that is written on the outer edge. In part, this is due to the mechanical action of the read/write head and the sectors of each track having to pass under the head. Data is more dense as it moves toward the center, resulting in less physical movement of the head. This results in faster overall throughput.

Physical partitions are numbered consecutively, starting with number one, from the outer-most edge to the inner-most edge.

The edge and inner-edge strategies specify allocation of partitions to the edges of the physical volume. These partitions have the slowest average seek times, which generally result in longer response times for any application that uses them. Edge on disks produced since the mid-1990s can hold more sectors per track so that the edge is faster for sequential I/O.

The middle and inner-middle strategies specify to avoid the edges of the physical volume and out of the center when allocating partitions. These strategies allocate reasonably good locations for partitions with reasonably good average seek times. Most of the partitions on a physical volume are available for allocation using this strategy.

The center strategy specifies allocation of partitions to the center section of each physical volume. These partitions have the fastest average seek times, which generally result in the best response time for any application that uses them. Fewer partitions on a physical volume satisfy the center strategy than any other general strategy.

The paging space logical volume is a good candidate for allocation at the center of a physical volume if there is lot of paging activity. At the other extreme, the dump and boot logical volumes are used infrequently and, therefore, should be allocated at the beginning or end of the physical volume.

The general rule, then, is that the more I/Os, either absolutely or in the course of running an important application, the closer to the center of the physical volumes the physical partitions of the logical volume should be allocated.

Range of Physical Volumes

The *Inter-Physical Volume Allocation Policy* specifies which strategy should be used for choosing physical devices to allocate the physical partitions of a logical volume. The choices are the minimum and maximum options.

Maximum Inter-Disk Policy (Range=maximum) with a Single Logical Volume Copy per Disk (Strict=y)

Figure 20. Inter-Physical Volume Allocation Policy. This illustration shows 2 physical volumes. One contains partition 1 and a copy of partition 2. The other contains partition 2 with a copy of partition 1. The formula for allocation is Maximum Inter-Disk Policy (Range=maximum) with a Single Logical Volume Copy per Disk (Strict=y).

The minimum option indicates the number of physical volumes used to allocate the required physical partitions. This is generally the policy to use to provide the greatest reliability and availability, without having copies, to a logical volume. Two choices are available when using the minimum option, with copies and without, as follows:

- Without Copies: The minimum option indicates one physical volume should contain all the physical partitions of this logical volume. If the allocation program must use two or more physical volumes, it uses the minimum number possible, remaining consistent with the other parameters.
- With Copies: The minimum option indicates that as many physical volumes as there are copies should be used. If the allocation program must use two or more physical volumes, the minimum number of physical volumes possible are used to hold all the physical partitions. At all times, the constraints imposed by other parameters such as the strict option are observed.

These definitions are applicable when extending or copying an existing logical volume. The existing allocation is counted to determine the number of physical volumes to use in the minimum with copies case, for example.

The maximum option indicates the number of physical volumes used to allocate the required physical partitions. The maximum option intends, considering other constraints, to spread the physical partitions of this logical volume over as many physical volumes as possible. This is a performance-oriented option and should be used with copies to improve availability. If an uncopied logical volume is spread across multiple physical volumes, the loss of any physical volume containing a physical partition from that logical volume is enough to cause the logical volume to be incomplete.

Maximum Number of Physical Volumes to Use for Allocation

Sets the maximum number of physical volumes for new allocation. The value should be between one and the total number of physical volumes in the volume group. This option relates to Range of Physical Volumes.

Mirror Write Consistency

The LVM always ensures data consistency among mirrored copies of a logical volume during normal I/O processing. For every write to a logical volume, the LVM generates a write request for every mirror copy. A problem arises if the system crashes in the middle of processing a mirrored write (before all copies are written). If mirror write consistency recovery is requested for a logical volume, the LVM keeps additional information to allow recovery of these inconsistent mirrors. Mirror write consistency recovery should be performed for most mirrored logical volumes. Logical volumes, such as the page space that do not use the existing data when the volume group is re-varied on, do not need this protection.

The Mirror Write Consistency (MWC) record consists of one sector. It identifies which logical partitions may be inconsistent if the system is not shut down correctly. When the volume group is varied back on-line, this information is used to make the logical partitions consistent again.

Note: With Mirror Write Consistency LVs, because the MWC control sector is on the edge of the disk, performance may be improved if the mirrored logical volume is also on the edge.

MWC can take two writes just to perform one write. What are the implications if MWC is turned off? The answer is that the user is now responsible for:

1. Turning off `autovaryon` on the volume group.
2. Manually running the `syncvg -f` command onto the volume group.

This is the trade-off between speed and reliability.

Allocate Each Logical Partition Copy on a Separate PV

Specifies whether to follow the strict allocation policy. Strict allocation policy allocates each copy of a logical partition on a separate physical volume. This option relates to Range of Physical Volumes.

Relocate the Logical Volume During Reorganization?

Specifies whether to allow the relocation of the logical volume during reorganization. For striped logical volumes, the `relocate` parameter must be set to `no` (the default for striped logical volumes). Depending on your installation you may want to relocate your logical volume.

Scheduling Policy for Reading/Writing Logical Partition Copies

Different scheduling policies can be set for the logical volume. Different types of scheduling policies are used for logical volumes with multiple copies, as follows:

- The *parallel* policy balances reads between the disks. On each read, the system checks whether the primary is busy. If it is not busy, the read is initiated on the primary. If the primary is busy, the system checks the secondary. If it is not busy, the read is initiated on the secondary. If the secondary is busy, the read is initiated on the copy with the least number of outstanding I/Os. Writes are initiated concurrently.
- The *parallel/sequential* policy always initiates reads on the primary copy. Writes are initiated concurrently.
- The *parallel/round robin* policy is similar to the *parallel* policy except that instead of always checking the primary copy first, it alternates between the copies. This results in equal utilization for reads even when there is never more than one I/O outstanding at a time. Writes are initiated concurrently.
- The *sequential* policy results in all reads being issued to the primary copy. Writes happen serially, first to the primary disk; only when that is completed is the second write initiated to the secondary disk.

For data that has only one physical copy, the logical volume device driver translates a logical read or write request address into a physical address and calls the appropriate physical device driver to service the request. This single-copy policy handles Bad Block Relocation for write requests and returns all read errors to the calling process.

Mirroring-scheduling policies, such as *parallel* and *parallel/round-robin*, can allow performance on read-intensive mirrored configurations to be equivalent to non-mirrored ones. Typically, performance on write-intensive mirrored configurations is less than non-mirrored, unless more disks are used.

Enable Write Verify

Specifies whether to verify all writes to the logical volume with a follow-up read. Setting this to `Yes` has an impact on performance.

Striping Size

When defining a striped logical volume, at least two physical drives are required. Stripe size can be any power of 2 from 4 KB to 128 KB. The size of the logical volume in partitions must be an integral multiple of the number of disk drives used. See Tuning Logical Volume Striping for a detailed discussion.

Physical Volume Considerations

The major performance issue for disk drives is application-related; that is, whether large numbers of small accesses will be made (random), or smaller numbers of large accesses (sequential). For random access, performance will generally be better using larger numbers of smaller capacity drives. The opposite situation exists for sequential access (use faster drives or use striping with larger number of drives).

Volume Group Recommendations

If possible, for easier system management and better performance, the default volume group, rootvg, should consist of only the physical volume on which the operating system is initially installed. Maintaining only operating systems in the rootvg is a good decision because operating system updates, reinstallations, and crash recovery can be accomplished without endangering user data. Updates and reinstallations can be done more quickly because only the operating system is included in the changes.

One or more other volume groups should be defined for the other physical volumes that hold the user data. Having user data in alternate volume groups allows easier exporting of that data to other systems.

Place a highly active file system on one disk and the log for that file system on another if the activity would generate a lot of log transactions (see Reorganizing JFS Log and Log Logical Volumes). Cached devices (such as solid-state disks, SSA with Fast Write Cache, or disk arrays with write-cache) can provide for much better performance for log logical volumes (JFS log or database logs).

Performance Impacts of Mirroring rootvg

Although mirroring is common for customer data, particularly in database environments, it is used less frequently for system volumes.

In mirroring, when a write occurs, it must occur to at least two disks in parallel. Typically, this write will take longer than if the disk was not mirrored. Mirroring can also cause additional CPU overhead, because two disk I/Os take more instructions to complete than one. It is important to understand the layout of the rootvg logical volumes so one can guess where problems might exist when mirroring the rootvg logical volumes.

Looking at logical volumes typically found in rootvg, we expect most of the files in */*, including the heavily used */usr/bin* where many executable programs reside, to be read-mostly data. The paging space should have writes only if the amount of physical memory in the system is insufficient to hold the current level of activity. It is common for systems to page from time to time, but sustained heavy paging usually leads to poor response time. The addition of physical memory generally resolves this issue.

The */tmp* and */var* file systems do see file-write activity for many types of applications. Applications, such as the compiler, often create and write temporary files in the */tmp* directory. The */var* directory receives files destined for mail and printer queues. The *jfslog* is essentially write-only during normal operation. Of the remaining file systems, perhaps only the */home* directory is active during normal operation. Frequently, user home directories are placed in other file systems, which simplifies rootvg management.

The rootvg can be mirrored by mirroring each logical volume in rootvg with the **mkivcopy** command; or in AIX 4.2.1 and later, rootvg can be mirrored using the **mirrorvg** command.

By default, the **mirrorvg** command uses the parallel scheduling policy and leaves write-verify off for all logical volumes. It does not enable mirror-write consistency for page space. It does enable mirror-write

consistency for all other logical volumes. Place logical volumes that are written to frequently close to the outer edge of the disk to minimize seek distance between the logical volume and the mirror-write consistency cache.

The caveat to mirroring rootvg not significantly affecting performance is that, if paging space is mirrored, the slowdown is directly related to paging rate. So systems that are configured to support very high paging rates, with paging spaces on rootvg, might not want to implement rootvg mirroring.

In summary, mirrored rootvg might be worth considering if your workload does not have high sustained paging rates.

Reorganizing Logical Volumes

If you find that a volume was sufficiently fragmented to require reorganization, you can use the **reorgvg** command (or **smitty reorgvg**) to reorganize a logical volume and make it adhere to the stated policies. This command will reorganize the placement of physical partitions within the volume group according to the logical volume characteristics. If logical volume names are specified with the command, highest priority is given to the first logical volume in the list. To use this command, the volume group must be varied on and have free partitions. The relocatable flag of each logical volume must be set to yes for the reorganization to take place, otherwise the logical volume is ignored.

By knowing the usage pattern of logical volumes, you can make better decisions governing the policies to set for each volume. Guidelines are:

- Allocate hot LVs to different PVs.
- Spread hot LV across multiple PVs.
- Place hottest LVs in center of PVs, except for LVs that have Mirror Write Consistency Check turned on.
- Place coldest LVs on Edges of PVs (except when accessed sequentially).
- Make LV contiguous.
- Define LV to maximum size that you will need.
- Place frequently used logical volumes close together.
- Place sequential files on the edge.

Recommendations for Best Performance

Whenever logical volumes are configured for better performance, the availability might be impacted. Decide whether performance or availability is more critical to your environment.

Use these guidelines when configuring for highest performance with the SMIT command:

- If the system does mostly reads, then mirroring with scheduling policy set to parallel can provide for better performance since the read I/Os will be directed to the copies that are least busy. If doing writes, then mirroring will cause a performance penalty because there will be multiple copies to write as well as the Mirror Write Consistency record to update. You may also want to set the allocation policy to Strict to have each copy on a separate physical volume.
- Set the write verify policy to No and, if the number of copies is greater than one, set the Mirror Write Consistency to Off.
- In general, the most frequently accessed logical volumes should be in the center in order to minimize seek distances; however, there are some exceptions:
 - Disks hold more data per track on the edges of the disk. Logical volumes being accessed in sequential manner could be placed on the edge for better performance.
 - Another exception is for logical volumes that have Mirror Write Consistency Check (MWCC) turned on. Because the MWCC sector is on the edge of the disk, performance may be improved if the mirrored logical volume is also on the edge.

- Logical volumes that will be accessed frequently or concurrently should be placed close together on the disk. Locality of reference is more important than placing them in the center.
- Put moderately used logical volumes in the middle, and put seldom-used logical volumes on the edge.
- By setting the Inter-Physical Volume Allocation Policy to maximum, you also ensure that the reads and writes are shared among PVs.

Recommendations for Highest Availability

To configure the system for highest availability (with the SMIT command), follow these guidelines:

- Use three LP copies (mirroring twice)
- Set write verify to Yes
- Set the inter policy to Minimum (mirroring copies = # of PVs)
- Set the scheduling policy to Sequential
- Set the allocation policy to Strict (no mirroring on the same PV)
- Include at least three physical volumes in a volume group
- Mirror the copies on physical volumes attached to separate buses, adapters, and power supplies

Having at least three physical volumes allows a quorum to be maintained in the event one physical volume becomes unavailable. Using separate busses, adapters, and power allows the use of copies not attached to the failing device.

Reorganizing File Systems

You can reduce file system fragmentation as follows:

- Copying the files to a backup media
- Recreating the file system using the **mkfs** *fsname* command or deleting the contents of the file system
- Reloading the files into the new file system

This procedure loads the file sequentially and reduces fragmentation.

Reorganizing a File System

For example, a system has a separate logical volume and file system `hd11` (mount point: `/home/op`). Because we decide that file system `hd11` needs to be reorganized, we perform the following steps:

1. Back up the file system by file name. If you back up the file system by i-node instead of by name, the **restore** command puts the files back in their original places, which would not solve the problem. Run the following commands:

```
# cd /home/op
# find . -print | backup -ivf/tmp/op.backup
```

This command creates a backup file (in a different file system), containing all of the files in the file system that is to be reorganized. If disk space on the system is limited, you can use tape to back up the file system.

2. Run the following commands:

```
# cd /
# unmount /home/op
```

If any processes are using `/home/op` or any of its subdirectories, you must terminate those processes before the **unmount** command can complete successfully.

3. Re-create the file system on the `/home/op` logical volume, as follows:

```
# mkfs /dev/hd11
```

You are prompted for confirmation before the old file system is destroyed. The name of the file system does not change.

4. To restore the original situation (except that **/home/op** is empty), run the following:

```
# mount /dev/hd11 /home/op
# cd /home/op
```

5. Restore the data, as follows:

```
# restore -xvf/tmp/op.backup >/dev/null
```

Standard output is redirected to **/dev/null** to avoid displaying the name of each of the files that were restored, which is time-consuming.

6. Review the large file inspected earlier (see *Assessing File Placement with the fileplace Command*), as follows

```
# fileplace -piv big1
```

We see that it is now (nearly) contiguous:

```
File: big1 Size: 3554273 bytes Vol: /dev/hd11
Blk Size: 4096 Frag Size: 4096 Nfrags: 868 Compress: no
Inode: 8290 Mode: -rwxr-xr-x Owner: hoetzel Group: system
```

INDIRECT BLOCK: 60307

Physical Addresses (mirror copy 1)	Logical Fragment
-----	-----
0060299-0060306 hdisk1 8 frags 32768 Bytes, 0.9%	0008555-0008562
0060308-0061167 hdisk1 860 frags 3522560 Bytes, 99.1%	0008564-0009423

```
868 frags over space of 869 frags: space efficiency = 99.9%
2 fragments out of 868 possible: sequentiality = 99.9%
```

The **-i** option that we added to the **fileplace** command indicates that the one-block gap between the first eight blocks of the file and the remainder contains the indirect block, which is required to supplement the i-node information when the length of the file exceeds eight blocks.

Some file systems or logical volumes should not be reorganized because the data is either transitory (for example, **/tmp**) or not in a file system format (log). The root file system is normally not very volatile and seldom needs reorganizing. It can only be done in install/maintenance mode. The same is true for **/usr** because many of these files are required for normal system operation.

Defragmenting a File System

If a journaled file system has been created with a fragment size smaller than 4 KB, it becomes necessary after a period of time to query the amount of scattered unusable fragments. If many small fragments are scattered, it is difficult to find available contiguous space.

To recover these small, scattered spaces, use the **smitty dejfs** command or the **defragfs** command. Some free space must be available for the defragmentation procedure to be used. The file system must be mounted for read-write.

Reorganizing JFS Log and Log Logical Volumes

The Journaled File System (JFS) uses a database journaling technique to maintain a consistent file system structure. This involves duplicating transactions that are made to file system metadata to the circular JFS log. File system metadata includes the superblock, i-nodes, indirect data pointers, and directories.

When pages in memory are actually written to disk by a **sync()** or **fsync()** call, commit records are written to the JFS log to indicate that the data is now on disk. JFS log transactions occur in the following situations:

- When a file is created or deleted.
- When a **write()** call occurs for a file opened with `O_SYNC` and the write causes a new disk block allocation.
- When the **fsync()** or **sync()** subroutines are called.
- When a write causes an indirect or double-indirect block to be allocated.

JFS logs enable rapid and clean recovery of file systems if a system goes down. If an application is doing synchronous I/O or is creating and removing many files in a short amount of time, there might be a lot of I/O going to the JFS log logical volume. If both the JFS log logical volume and the file system logical volume are on the same physical disk, this could cause an I/O bottleneck. The recommendation would be to migrate the JFS log device to another physical disk (this is especially useful for NFS servers).

Fast-write cached devices can provide for much better performance for log logical volumes (JFS log or database logs).

AIX 4.3.2 provides a **mount** option called **nointegrity** which bypasses the use of a JFS log for the file system mounted with this option. This can provide better performance as long as the administrator knows that the **fsck** command might have to be run on the file system if the system goes down without a clean shutdown.

Use the **filemon** command to record information about I/Os to the JFS log. If you notice that a file system and its log device are both heavily utilized, it might be better to put each one on a separate physical disk (assuming that there is more than one disk in that volume group).

You can have multiple log devices in a volume group. However, a log for a file system must be in the same volume group as that of the file system. A log logical volume or file system logical volume can be moved to another disk using the **migratepv** command, even while the system is running and in use.

Creating Log Logical Volumes

Placing the log logical volume on a physical volume different from your most active file system logical volume will increase parallel resource usage. You can use a separate log for each file system.

When you create your logical volumes, the performance of drives differs. Try to create a logical volume for a hot file system on a fast drive (possibly one with fast write cache), as follows:

1. Create new JFS log logical volume, as follows:

```
# mklv -t jfslog -y LVname VGname 1 PVname
```

OR

```
# smitty mklv
```

2. Format the log as follows:

```
# /usr/sbin/logform /dev/LVname
```

3. Modify **/etc/filesystems** and the logical volume control block (LVCB) as follows:

```
# chfs -a log=/dev/LVname /filesystemname
```

4. Unmount and then mount file system.

Another way to create the log on a separate volume is to:

- Initially define the volume group with a single physical volume.
- Define a logical volume within the new volume group (this causes the allocation of the volume group JFS log to be on the first physical volume).

- Add the remaining physical volumes to the volume group.
- Define the high-utilization file systems (logical volumes) on the newly added physical volumes.

Tuning with vmtune

The **vmtune** command can be used to modify the VMM parameters that control the behavior of the memory-management subsystem. Some options are available to alter the defaults for LVM and file systems; the options dealing with disk I/O are discussed in the following sections.

To determine whether the **vmtune** command is installed and available, run the following command:

```
# ls1pp -lI bos.adt.samples
```

The executable program for the **vmtune** command is found in the **/usr/samples/kernel** directory. The **vmtune** command can only be executed by the root user. Changes made by this tool remain in place until the next reboot of the system. If a permanent change is needed, place an appropriate entry in the **/etc/inittab** file. For example:

```
vmtune:2:wait:/usr/samples/kernel/vmtune -P 50
```

Note: The **vmtune** command is in the samples directory because it is VMM-implementation dependent. The **vmtune** code that accompanies each release of the operating system is tailored specifically to the VMM in that release. Running the **vmtune** command from one release on a system with a different VMM release might result in an operating system failure. It is also possible that the functions of the **vmtune** command may change from release to release. Be sure to review the appropriate tuning information before using the **vmtune** command to change system parameters.

Sequential Read-Ahead

The VMM sequential read-ahead feature, described in Sequential-Access Read Ahead can enhance the performance of programs that access large files sequentially.

It is rare that tuning the sequential read-ahead feature (or turning it off) will enhance performance. Nevertheless, the performance analyst should understand how this feature interacts with the application and with other disk-I/O tuning parameters. The following illustrates a typical situation.

Figure 21. Sequential Read-Ahead Example. This illustration shows a row of blocks simulating a segmented track of file page numbers. These block segments are numbered 0, 1 through 3, 4 through 7, 8 through 15 and 16 through 23. The steps of a sequential read-ahead are found in the text immediately following the illustration.

In this example, **minpgahead** is 2 and **maxpgahead** is 8 (the defaults). The program is processing the file sequentially. Only the data references that have significance to the read-ahead mechanism are shown, designated by A through F. The sequence of steps is:

- A** The first access to the file causes the first page (page 0) of the file to be read. At this point, the VMM makes no assumptions about random or sequential access.
- B** When the program accesses the first byte of the next page (page 1), with no intervening accesses to other pages of the file, the VMM concludes that the program is accessing sequentially. It schedules **minpgahead** (2) additional pages (pages 2 and 3) to be read. Thus access B causes a total of 3 pages to be read.

- C** When the program accesses the first byte of the first page that has been read ahead (page 2), the VMM doubles the page-ahead value to 4 and schedules pages 4 through 7 to be read.
- D** When the program accesses the first byte of the first page that has been read ahead (page 4), the VMM doubles the page-ahead value to 8 and schedules pages 8 through 15 to be read.
- E** When the program accesses the first byte of the first page that has been read ahead (page 8), the VMM determines that the page-ahead value is equal to **maxpgahead** and schedules pages 16 through 23 to be read.
- F** The VMM continues reading **maxpgahead** pages when the program accesses the first byte of the previous group of read-ahead pages until the file ends.

If the program were to deviate from the sequential-access pattern and access a page of the file out of order, sequential read-ahead would be terminated. It would be resumed with **minpgahead** pages if the VMM detected that the program resumed sequential access.

The **minpgahead** and **maxpgahead** values can be changed by using options **-r** and **-R** in the **vmtune** command. If you are contemplating changing these values, keep in mind:

- The values should be from the set: 0, 1, 2, 4, 8, 16, and so on. The use of other values may have adverse performance or functional effects.
 - Values should be powers of 2 because of the doubling algorithm of the VMM.
 - Values of **maxpgahead** greater than 16 (reads ahead of more than 64 KB) exceed the capabilities of some disk device drivers. In such a case, the read size stays at 64 KB.
 - Higher values of **maxpgahead** can be used in systems where the sequential performance of striped logical volumes is of paramount importance.
- A **minpgahead** value of 0 effectively defeats the mechanism. This can adversely affect performance. However, it can be useful in some cases where I/O is random, but the size of the I/Os cause the VMM's read-ahead algorithm to take effect. Another case where turning off page-ahead is useful is the case of NFS reads on files that are locked. On these types of files, read-ahead pages are typically flushed by NFS so that reading ahead is not helpful. NFS and the VMM have been changed starting with AIX 4.3.3 to automatically turn off VMM read-ahead if it is operating on a locked file.
- The default **maxpgahead** value of 8 yields the maximum possible sequential I/O performance for currently supported disk drives.
- The buildup of the read-ahead value from **minpgahead** to **maxpgahead** is quick enough that for most file sizes there is no advantage to increasing **minpgahead**.

VMM Write-Behind

Write-behind involves asynchronously writing modified pages in memory to disk after reaching a threshold rather than waiting for the **syncd** daemon to flush the pages to disk. This is done to limit the number of dirty pages in memory, reduce system overhead, and minimize disk fragmentation. There are two types of write-behind: sequential and random.

Sequential Write-Behind

By default, a file is partitioned into 16 K partitions or 4 pages. Each of these partitions is called a *cluster*. If all 4 pages of this cluster are dirty, then as soon as a page in the next partition is modified, the 4 dirty pages of this cluster are scheduled to go to disk. Without this feature, pages would remain in memory until the **syncd** daemon runs, which could cause I/O bottlenecks and fragmentation of the file.

The number of clusters that the VMM uses as a threshold is tunable. The default is one cluster. You can delay write-behind by increasing the **numclust** parameter using the **vmtune -c** command.

Random Write-Behind

There may be applications that do a lot of random I/O, that is, the I/O pattern does not meet the requirements of the write-behind algorithm and thus all the pages stay resident in memory until the **syncd**

daemon runs. If the application has modified many pages in memory, this could cause a very large number of pages to be written to disk when the **syncd** daemon issues a **sync()** call.

The write-behind feature provides a mechanism such that when the number of dirty pages in memory for a given file exceeds a defined threshold, these pages are then scheduled to be written to disk.

The administrator can tune the threshold by using the **-W** option of the **vm tune** command. The parameter to tune is **maxrandwrt**; the default value is 0 indicating that random write-behind is disabled. Increasing this value to 128 indicates that once 128 memory-resident pages of a file are dirty, any subsequent dirty pages are scheduled to be written to the disk. The first set of pages will be flushed after a **sync()** call.

Tuning File Syncs

JFS file I/Os that are not sequential will accumulate in memory until certain conditions are met:

- The free list shrinks to **minfree**, and page replacement has to occur.
- The **syncd** daemon flushes pages at regularly scheduled intervals.
- The **sync** command is issued.
- Random-write-behind flushes the dirty pages after random-write-behind threshold is reached.

If too many pages accumulate before one of these conditions occur, then when pages do get flushed by the **syncd** daemon, the i-node lock is obtained and held until all dirty pages have been written to disk. During this time, threads trying to access that file will get blocked because the i-node lock is not available. Remember that the **syncd** daemon currently flushes all dirty pages of a file, but one file at a time. On systems with large amount of memory and large numbers of pages getting modified, high peaks of I/Os can occur when the **syncd** daemon flushes the pages.

A tunable option called **sync_release_ilock** has been added in AIX 4.3.2. The **vm tune** command with the **-s** option (value of 1 means release the i-node lock while flushing the modified pages, 0 means old behavior) allows the i-node lock to be released while dirty pages of that file are being flushed. This can result in better response time when accessing this file during a **sync()** call.

This blocking effect can also be minimized by increasing the frequency of syncs in the **syncd** daemon. Change **/sbin/rc.boot** where it invokes the **syncd** daemon. Then reboot the system for it to take effect. For the current system, kill the **syncd** daemon and restart it with the new seconds value.

A third way to tune this behavior is by turning on random write-behind using the **vm tune** command (see VMM Write-Behind).

Miscellaneous I/O Tuning Parameters

The following **vm tune** parameters can be useful in tuning disk I/O:

numfsbufs

If there are many simultaneous or large I/Os to a filesystem or if there are large sequential I/Os to a file system, it is possible that the I/Os might bottleneck at the file system level while waiting for bufstructs. The number of bufstructs per file system (known as **numfsbufs**) can be increased using the **vm tune -b** command. The value takes effect only when a file system is mounted; so if you change the value, you must first unmount and mount the file system again. The default value for **numfsbufs** is currently 93 bufstructs per file system.

lvm_bufcnt

If an application is issuing very large raw I/Os rather than writing through the file system, the same type of bottleneck as for file systems could occur at the LVM layer. Very large I/Os combined with very fast I/O devices would be required to cause the bottleneck to be at the LVM layer. But if it does happen, a parameter called **lvm_bufcnt** can be increased by the **vm tune -u** command to provide for a larger number of "uphysio" buffers. The value takes effect immediately. The current default value is 9 "uphysio" buffers.

Because the LVM currently splits I/Os into 128 K each, and because the default value of **lvm_bufcnt** is 9, the 9*128 K can be written at one time. If you are doing I/Os that are larger than 9*128 K, then increasing **lvm_bufcnt** may be advantageous.

hd_pbuf_cnt

The **hd_pbuf_cnt** parameter (**-B**) controls the number of pbufs available to the LVM device driver. Pbufs are pinned memory buffers used to hold I/O requests that are pending at the LVM layer.

In AIX Version 4, coalescing of sequential I/Os is done so that a single pbuf is used for each sequential I/O request regardless of the number of pages in that I/O. It is difficult to encounter this type of bottleneck. With random I/O, the I/Os tend to get flushed sporadically with the exception of the case when the **syncd** daemon runs.

The best way to determine if a pbuf bottleneck is occurring is to examine a LVM variable called **hd_pendqblked**. The following script can provide the value of this variable:

```
#!/bin/ksh
# requires root authority to run
# determines number of times LVM had to wait on pbufs since system boot
addr='echo "knlist hd_pendqblked" | /usr/sbin/crash 2>/dev/null | tail -1 | cut -f2 -d:'
value='echo "od $addr 1 D" | /usr/sbin/crash 2>/dev/null | tail -1 | cut -f2 -d:'
echo "Number of waits on LVM pbufs are: $value"
exit 0
```

Starting with AIX 4.3.3, the command **vmtune -a** also displays the **hd_pendqblked** value (see **fsbufwaitcnt** and **psbufwaitcnt**).

Note: Do not set the **hd_pbuf_cnt** value too high, because the value cannot be lowered without a system reboot.

pd_npages

Specifies the number of pages that should be deleted in one chunk from RAM when a file is deleted. Changing this value may only be beneficial to real-time applications that delete files. By reducing the value of **pd_npages**, a real-time application can get better response time because few number of pages will be deleted before a process/thread is dispatched. The default value is the largest possible file size divided by the page size (currently 4096); if the largest possible file size is 2 GB, then **pd_npages** is 524288 by default. It can be changed with option **-N**.

v_pinshm

When you set the **v_pinshm** parameter to 1 (**-S 1**), it causes pages in shared memory segments to be pinned by VMM, if the application, which does the **shmget()**, specifies **SHM_PIN** as part of the flags. The default value is 0. This option is only available with operating system 4.3.3 and later.

Applications can choose to have a tunable which specifies whether the application should use the **SHM_PIN** flag (for example, the **lock_sga** parameter in Oracle 8.1.5 and later). Avoid pinning too much memory, because in that case no page replacement can occur. Pinning is useful because it saves overhead in async I/O from these shared memory segments (the async I/O kernel extension are not required to pin the buffers).

fsbufwaitcnt and psbufwaitcnt

Two new counters were added in AIX 4.3.3, which are incremented whenever a bufstruct was not available and the VMM puts a thread on the VMM wait list. Examine the values of these counters (**fsbufwaitcnt** and **psbufwaitcnt**) using the **crash** command or with a new option for the **vmtune** command (**-a**). Following is an example output:

```
# vmtune -a
hd_pendqblked = 305
psbufwaitcnt = 0
fsbufwaitcnt = 337
```

Using Disk-I/O Pacing

Disk-I/O pacing is intended to prevent programs that generate very large amounts of output from saturating the system's I/O facilities and causing the response times of less-demanding programs to deteriorate. Disk-I/O pacing enforces per-segment (which effectively means per-file) high- and low-water marks on the sum of all pending I/Os. When a process tries to write to a file that already has *high-water mark* pending writes, the process is put to sleep until enough I/Os have completed to make the number of pending writes less than or equal to the *low-water mark*. The logic of I/O-request handling does not change. The output from high-volume processes is slowed down somewhat.

The high- and low-water marks are set with the SMIT command by selecting **System Environments -> Change / Show Characteristics of Operating System(smitty chgsys)** and then entering the number of pages for the high- and low-water marks. The default value for the high- and low-water marks is 0, which disables pacing. Changes to the **maxpout** and **minpout** values take effect immediately and remain in place until they are explicitly changed.

Example

The effect of pacing on performance can be demonstrated with an experiment that consists of starting a **vi** editor session on a new file while another process is copying a 64 MB file with the **cp** command. The file is copied from **hdisk1** to **hdisk0** and the **vi** executable program is located on **hdisk0**. For the **vi** session to start, it must page itself in as well as perform a few other I/Os, which it does randomly one page at a time. This takes about 50 physical I/Os, which can be completed in 0.71 seconds on a slow machine when there is no contention for the disk. With the high-water mark set to the default of 0, the logical writes from the **cp** command run ahead of the physical writes, and a large queue builds up.

Each I/O started by the **vi** session must wait its turn in the queue before the next I/O can be issued, and thus the **vi** command is not able to complete its needed I/O until after the **cp** command finishes. The following table shows the elapsed seconds for **cp** execution and **vi** initialization with different pacing parameters.

High-Water Mark	Low-Water Mark	cp (sec)	vi (sec)
0	0	50	vi not done
0	0	50	vi finished after cp
9	6	77	2.7
17	8	64	3.4
17	12	58	3.6
33	16	55	4.9
33	24	52	9.0

It is important to notice that the **cp** duration is always longer when pacing is set. Pacing sacrifices some throughput on I/O-intensive programs to improve the response time of other programs. The challenge for a system administrator is to choose settings that result in a throughput/response-time trade-off that is consistent with the organization's priorities.

The high- and low-water marks were chosen by trial and error, based on our knowledge of the I/O path. Choosing them is not straightforward because of the combination of write-behind and asynchronous writes. High-water marks of $(4 * n) + 1$, where n is a positive integer, work particularly well, because of the following interaction:

- The write-behind feature sends the previous four pages to disk when a logical write occurs to the first byte of the fifth page.

- If the pacing high-water mark were a multiple of 4 (for example, 8), a process would hit the high-water mark when it requested a write that extended into the 9th page. It would then be put to sleep, before the write-behind algorithm had an opportunity to detect that the fourth dirty page is complete and the four pages were ready to be written.
- The process would then sleep with four full pages of output until its outstanding writes fell below the pacing low-water mark.
- If, on the other hand, the high-water mark had been set to 9, write-behind would get to schedule the four pages for output before the process was suspended.

One limitation of pacing is that it does not offer as much control when a process writes buffers larger than 4 KB. When a write is sent to the VMM and the high-water mark has not been met, the VMM performs start I/Os on all pages in the buffer, even if that results in exceeding the high-water mark. Pacing works well on the **cp** command because the **cp** command writes 4 KB at a time; but if the **cp** command wrote larger buffers, the times shown in the previous table for starting the **vi** session would increase.

Disk-I/O pacing is a tuning parameter that can improve interactive response time in some situations where foreground or background programs that write large volumes of data are interfering with foreground requests. If not used properly, however, it can reduce throughput excessively. The settings in the previous table are a good place to start, but some experimenting will be needed to find the best settings for your workload. For the newer systems, view these numbers as the minimum starting point.

Programs whose presence in a workload may make imposition of disk-I/O pacing necessary include:

- Programs that generate large amounts of output algorithmically, and thus are not constrained by the time required to read input. Some such programs may need pacing on comparatively fast processors and not need it on comparatively slow processors.
- Programs that write large, possibly somewhat modified, files that have been read in their entirety shortly before writing begins (by a previous command, for example).
- Filters, such as the **tar** command, that read a file and write it out again with little processing. The need for pacing can be exacerbated if the input is being read from a faster disk drive than the output is being written to.

Tuning Logical Volume Striping

Striping is a technique for spreading the data in a logical volume across several disk drives in such a way that the I/O capacity of the disk drives can be used in parallel to access data on the logical volume. The primary objective of striping is very high-performance reading and writing of large sequential files, but there are also benefits for random access. The following illustration gives a simple example.

Figure 22. Striped Logical Volume /dev/lvs0. This illustration shows three physical volumes or drives. Each physical drive is partitioned into two logical volumes. The first partition, or logical volume, of drive 1 contains stripe unit 1 and 4. Partition 1 of drive 2 contains stripe unit 2 and 5 and partition 1 of drive 3 contains stripe unit 3 and 6. The second partition of drive one contains stripe unit n and n+3. The second partition of drive 2 contains stripe unit n+1 and n+4. Partition 2 of drive 3 contains stripe unit n+2 and n+5.

In an ordinary logical volume, the data addresses correspond to the sequence of blocks in the underlying physical partitions. In a striped logical volume, the data addresses follow the sequence of stripe units. A complete stripe consists of one stripe unit on each of the physical devices that contains part of the striped logical volume. The LVM determines which physical blocks on which physical drives correspond to a block being read or written. If more than one drive is involved, the necessary I/O operations are scheduled for all drives simultaneously.

As an example, a hypothetical lvs0 has a stripe-unit size of 64 KB, consists of six 2 MB partitions, and contains a journaled file system (JFS). If an application is reading a large sequential file and read-ahead has reached a steady state, each read will result in two or three I/Os being scheduled to each of the disk drives to read a total of eight pages (assuming that the file is on consecutive blocks in the logical volume). The read operations are performed in the order determined by the disk device driver. The requested data is assembled from the various pieces of input and returned to the application.

Although each disk device will have a different initial latency, depending on where its accessor was at the beginning of the operation, after the process reaches a steady state, all three disks should be reading at close to their maximum speed.

Designing a Striped Logical Volume

When a striped logical volume is defined, you specify:

drives At least two physical drives are required. The drives used should have little other activity when the performance-critical sequential I/O is taking place. Some combinations of disk adapter and disk drive will require dividing the workload of a striped logical volume between two or more adapters.

stripe unit size

Although this can be any power of 2 from 4 KB through 128 KB, take sequential read-ahead into

account, because that will be the mechanism that issues most of the reads. The objective is to have each read-ahead operation result in at least one I/O, ideally an equal number, to each disk drive (see previous figure).

size The number of physical partitions allocated to the logical volume must be an integral multiple of the number of disk drives used.

attributes

Beginning with AIX 4.3.3, striped logical volumes can be mirrored; that is, copies can now be set to more than 1.

Tuning for Striped Logical Volume I/O

Sequential and random disk I/Os benefit from disk striping. The following techniques have yielded the highest levels of sequential I/O throughput:

- Spread the logical volume across as many physical volumes as possible.
- Use as many adapters as possible for the physical volumes.
- Create a separate volume group for striped logical volumes.
- Set a stripe-unit size of 64 KB.
- Set **minpgahead** to 2 (**vmtune -r**). See Sequential Read-Ahead.
- Set **maxpgahead** to 16 times the number of disk drives (**vmtune -R**). This causes page-ahead to be done in units of the stripe-unit size (64 KB) times the number of disk drives, resulting in the reading of one stripe unit from each disk drive for each read-ahead operation.
- Request I/Os for 64 KB times the number of disk drives. This is equal to the **maxpgahead** value.
- Modify **maxfree** (**vmtune -F**) to accommodate the change in **maxpgahead** (**maxfree = minfree + maxpgahead**). See Choosing minfree and maxfree Settings.
- Use 64-byte aligned I/O buffers. If the logical volume will occupy physical drives that are connected to two or more disk adapters, the I/O buffers used should be allocated on 64-byte boundaries. This avoids having the LVM serialize the I/Os to the different disks. The following code would yield a 64-byte-aligned buffer pointer:

```
char *buffer;
buffer = malloc(MAXBLKSIZE+64);
buffer = ((int)buffer + 64) & ~0x3f;
```

If the striped logical volumes are on raw logical volumes and writes larger than 1.125 MB are being done to these striped raw logical volumes, increasing the **lvm_bufcnt** parameter with the command **vmtune -u** might increase throughput of the write activity. See Miscellaneous I/O Tuning Parameters.

Also, it is not a good idea to mix striped and non-striped logical volumes in the same physical volume. All physical volumes should be the same size within a set of striped logical volumes.

Mirrored Striped Logical Volume Performance Implications

AIX 4.3.3 allows striping and mirroring together on the same logical volume. This feature provides a convenient mechanism for high-performance redundant storage. Measurements indicate that read and file system write performance of striping and mirroring is approximately equal to the unmirrored case, assuming you have twice as many disks.

File system writes benefit from caching in the file system, which allows considerable overlap of writes to disk with the program initiating the writes. The raw write performance suffers. Because it is synchronous, both writes must complete before control is returned to the initiating program. Performing larger writes increases raw write throughput. Also, Mirror Write Consistency (MWC) affects the performance of this case.

In summary, striping and mirroring allow redundant storage for very high-performance access.

Tuning Asynchronous Disk I/O

An application's processing cannot continue until the I/O operation is complete. In contrast, asynchronous I/O operations run in the background and do not block user applications. This improves performance, because I/O operations and applications processing can run simultaneously. Many applications, such as databases and file servers, take advantage of the ability to overlap processing and I/O.

Applications can use the **aio_read()**, **aio_write()**, or **lio_listio()** subroutines (or their 64-bit counterparts) to perform asynchronous disk I/O. Control returns to the application from the subroutine as soon as the request has been queued. The application can then continue processing while the disk operation is being performed.

To manage asynchronous I/O, each asynchronous I/O request has a corresponding control block in the application's address space. This control block contains the control and status information for the request. It can be used again when the I/O operation is completed.

After issuing an asynchronous I/O request, the user application can determine when and how the I/O operation is completed. This information is provided in any of three ways:

- The application can poll the status of the I/O operation.
- The system can asynchronously notify the application when the I/O operation is done.
- The application can block until the I/O operation is complete.

In AIX Version 4, async I/O on JFS file systems is handled by kprocs. Async I/O on raw logical volume partitions is handled directly by the kernel. Starting with AIX 4.3.2 (and with a PTF for 4.3.1), Virtual Shared Disk (VSD) devices do not use kprocs.

Each I/O is handled by a single kproc, and typically the kproc cannot process any more requests from the queue until that I/O has completed. The default minimum number of servers configured when async I/O is enabled is 1. This is the **minservers** attribute. There is also a maximum number of async I/O servers that can get created which is controlled by the **maxservers** attribute; this has a default value of 10. The number of servers limits the number of asynchronous disk I/O operations that can be in progress in the system simultaneously. The number of servers can be set with the SMIT command (**smitty**->Devices->Asynchronous I/O->Change/Show Characteristics of Asynchronous I/O->{*MINIMUM* | *MAXIMUM*} number of servers or **smitty aio**) or with the **chdev** command.

In systems that seldom run applications that use asynchronous I/O, the defaults are usually adequate.

If the number of async I/O requests is high, then the recommendation is to increase **maxservers** to approximately the number of simultaneous I/Os there might be. In most cases, it is better to leave the **minservers** parameter at the default value because the AIO kernel extension will generate additional servers if needed.

Note: AIO actions performed against a raw Logical Volume do not use kproc server processes. The setting of **maxservers** and **minservers** have no effect in this case.

By looking at the CPU utilization of the AIO servers, if the utilization is evenly divided among all of them, that means that they're all being used; you may want to try increasing them in this case. To see the AIO servers by name, run the **pstat -a** command. Run the **ps -k** command to see the AIO servers as the name kproc.

For environments in which the performance of asynchronous disk I/O is critical and the volume of requests is high, but you do not have an approximate number of simultaneous I/Os, it is recommended that **maxservers** be set to at least 10*(number of disks accessed asynchronously).

This could be achieved for a system with three asynchronously accessed disks as follows:

```
# chdev -l aio0 -a maxservers='30'
```

In addition, you can set the maximum number of asynchronous I/O REQUESTS outstanding, and the server PRIORITY. If you have a system with a high volume of asynchronous I/O applications, it might be appropriate to increase the REQUESTS number and lower the PRIORITY number.

Tuning Direct I/O

When you are processing normal I/O to JFS files, the I/O goes from the application buffer to the VMM and from there to the JFS. The contents of the buffer could get cached in RAM through the VMM's use of real memory as a file buffer cache. If the file cache hit rate is high, then this type of cached I/O is very effective by improving performance of JFS I/O. But applications that have poor cache hit rates or applications that do very large I/Os may not get much benefit from the use of normal cached I/O. In operating system version 4.3, direct I/O was introduced as an alternative I/O method for JFS files.

Direct I/O is only supported for program working storage (local persistent files). The main benefit of direct I/O is to reduce CPU utilization for file reads and writes by eliminating the copy from the VMM file cache to the user buffer. If the cache hit rate is low, then most read requests have to go to the disk. Writes are faster with normal cached I/O in most cases. But if a file is opened with O_SYNC or O_DSYNC (see Using sync/fsync Calls), then the writes have to go to disk. In these cases, direct I/O can benefit applications because the data copy is eliminated.

Another benefit is that it allows applications to avoid diluting the effectiveness of caching of other files. When a file is read or written, that file competes for space in the file cache which could cause other file data to get pushed out of the cache. If an application developer knows that certain files have poor cache-utilization characteristics, then only those files could be opened with O_DIRECT.

For direct I/O to work efficiently, the I/O request should be appropriate for the type of file system being used. The **finfo()** and **ffinfo()** subroutines can be used to query the offset, length, and address alignment requirements for fixed block size file systems, fragmented file systems, and bigfile file systems (direct I/O is not supported on compressed file systems). The information queried are contained in the structure **diocapbuf** as described in **/usr/include/sys/finfo.h**.

To avoid consistency issues, if there are multiple calls to open a file and one or more of the calls did not specify O_DIRECT and another open specified O_DIRECT, the file stays in the normal cached I/O mode. Similarly, if the file is mapped into memory through the **shmat()** or **mmap()** system calls, it stays in normal cached mode. If the last conflicting, non-direct access is eliminated, then the JFS will move the file into direct I/O mode (either by using the **close()**, **munmap()**, or **shmdt()** subroutines). Changing from normal mode to direct I/O mode can be expensive because all modified pages in memory will have to be flushed to disk at that point.

Direct I/O does not enhance raw I/O performance. Raw I/O performance is still slightly faster than direct I/O, but if you want the benefits of a JFS and enhanced performance, direct I/O is highly recommended.

Performance of Direct I/O Reads

Even though the use of direct I/O can reduce CPU usage, it typically results in longer elapsed times, especially for small I/O requests, because the requests would not be cached in memory.

Direct I/O reads cause synchronous reads from the disk, whereas with normal cached policy, the reads may be satisfied from the cache. This can result in poor performance if the data was likely to be in memory under the normal caching policy. Direct I/O also bypasses the VMM read-ahead algorithm because the I/Os do not go through the VMM. The read-ahead algorithm is very useful for sequential access to files because the VMM can initiate disk requests and have the pages already be resident in memory before the application has requested the pages. Applications can compensate for the loss of this read-ahead by using one of the following methods:

- Issuing larger read requests (minimum of 128 K)
- Issuing asynchronous direct I/O read-ahead by the use of multiple threads
- Using the asynchronous I/O facilities such as `aio_read()` or `lio_listio()`

Performance of Direct I/O Writes

Direct I/O writes bypass the VMM and go directly to the disk, so that there can be a significant performance penalty; in normal cached I/O, the writes can go to memory and then be flushed to disk later (write-behind). Because direct I/O writes do not get copied into memory, when a sync operation is performed, it will not have to flush these pages to disk, thus reducing the amount of work the `syncd` daemon has to perform.

Performance Example

In the following example, performance is measured on an RS/6000 E30, 233 MHz, with AIX 4.3.1 (your performance will vary, depending on system configuration). KBPS is the throughput in kilobytes per second, and %CPU is CPU usage in percent.

# of 2.2 GB SSA Disks	1	2	4	6	8
# of PCI SSA Adapters	1	1	1	1	1
Sequential read throughput, using normal I/O					
KBPS	7108	14170	18725	18519	17892
%CPU	23.9	56.1	92.1	97.0	98.3
Sequential read throughput, using direct I/O					
KBPS	7098	14150	22035	27588	30062
%CPU	4.4	9.1	22.0	39.2	54.4
Sequential read throughput, using raw I/O					
KBPS	7258	14499	28504	30946	32165
%CPU	1.6	3.2	10.0	20.9	24.5

Summary

Direct I/O requires substantially fewer CPU cycles than regular I/O. I/O-intensive applications that do not get much benefit from the caching provided by regular I/O can enhance performance by using direct I/O. The benefits of direct I/O will grow in the future as increases in CPU speeds continue to outpace increases in memory speeds.

What types of programs are good candidates for direct I/O? Programs that are typically CPU-limited and perform lots of disk I/O. "Technical" codes that have large sequential I/Os are good candidates. Applications that do numerous small I/Os will typically see less performance benefit, because direct I/O cannot do read ahead or write behind. Applications that have benefited from striping are also good candidates.

Using Raw Disk I/O

Sometimes applications may want to implement their own journaling; database applications are good examples. These applications can avoid duplicate logging (its own database logs and the JFS logs) by performing I/O directly to the raw logical volume and bypassing the JFS.

A program might access disk in raw mode in three ways:

- Block raw-disk-device special files have names of the form `/dev/hdiskn`, and are used by some subsystems. These devices should not be used by application programs.

- Character raw-disk-device special files have names of the form `/dev/rhdiskn`. Use of these devices by application programs is not recommended. If you decide to use this technique, make sure that no logical volumes occupy any part of the physical disk drive being accessed. The performance effect of interaction between raw access and file-system access to the same physical drive is unpredictable. Make sure you do not overwrite the first 512 bytes of the disk because that is where the physical volume ID is stored.
- A logical volume on which no file system has been created can be accessed in raw mode. All writes, reads, lseeks, and so on must be in multiples of 512 bytes. The least important consequence of violating this rule is serious performance degradation. The Logical Volume Control Block (LVCB) occupies the first 512 bytes of the logical volume. An application writing directly to the logical volume must ensure that it does not overwrite this LVCB.

Using sync/fsync Calls

If a file is opened with `O_SYNC` or `O_DSYNC`, then each write will cause the data for that write to be flushed to disk before the write returns. If the write causes a new disk allocation (the file is being extended instead of overwriting an existing page), then that write will also cause a corresponding JFS log write.

Forced synchronization of the contents of real memory and disk takes place in several ways:

- An application program makes an **fsync()** call for a specified file. This causes all of the pages that contain modified data for that file to be written to disk. The writing is complete when the **fsync()** call returns to the program.
- An application program makes a **sync()** call. This causes all of the file pages in memory that contain modified data to be scheduled for writing to disk. The writing is not necessarily complete when the **sync()** call returns to the program.
- A user can enter the **sync** command, which in turn issues a **sync()** call. Again, some of the writes may not be complete when the user is prompted for input (or the next command in a shell script is processed).
- The `/usr/sbin/syncd` daemon issues a **sync()** call at regular intervals, usually every 60 seconds. This ensures that the system does not accumulate large amounts of data that exists only in volatile RAM.

A sync operation has several effects, aside from its small CPU consumption:

- It causes writes to be clumped, rather than spread out.
- It causes at least 28 KB of system data to be written, even if there has been no I/O activity since the previous **sync** operation.
- It accelerates the writing of data to disk, defeating the write-behind algorithm. This effect is significant mainly in programs that issue an **fsync()** call after every write.
- When **sync()** or **fsync()** calls occur, log records are written to the JFS log device to indicate that the modified data has been committed to disk.

Setting SCSI-Adapter and Disk-Device Queue Limits

The operating system has the ability to enforce limits on the number of I/O requests that can be outstanding from the SCSI adapter to a given SCSI bus or disk drive. These limits are intended to exploit the hardware's ability to handle multiple requests while ensuring that the seek-optimization algorithms in the device drivers are able to operate effectively.

For non-IBM devices, it is sometimes appropriate to modify the default queue-limit values that have been chosen to handle the worst possible case. The following sections describe situations in which the defaults should be changed and the recommended new values.

Non-IBM Disk Drive

For IBM disk drives, the default number of requests that can be outstanding at any given time is 3 (8 for SSA). This value is based on complex performance considerations, and no direct interface is provided for changing it. The default hardware queue depth for non-IBM disk drives is 1. If a specific non-IBM disk drive does have the ability to buffer multiple requests, the system's description of that device should be changed accordingly.

As an example, the default characteristics of a non-IBM disk drive are displayed with the **lsattr** command, as follows:

```
# lsattr -D -c disk -s scsi -t osdisk
pvid          none Physical volume identifier      False
clr_q         no   Device CLEARS its Queue on error
q_err        yes  Use QERR bit
q_type       none Queuing TYPE
queue_depth  1   Queue DEPTH
reassign_to  120 REASSIGN time out value
rw_timeout   30  READ/WRITE time out value
start_timeout 60  START unit time out value
```

You can use SMIT (the fast path is **smitty chgdsk**) or the **chdev** command to change these parameters. For example, if your system contained a non-IBM SCSI disk drive `hdisk5`, the following command enables queuing for that device and sets its queue depth to 3:

```
# chdev -l hdisk5 -a q_type=simple -a queue_depth=3
```

Non-IBM Disk Array

A disk array appears to the operating system as a single, rather large, disk drive. A non-IBM disk array, like a non-IBM disk drive, is of class `disk`, subclass `SCSI`, type `osdisk` (which stands for "Other SCSI Disk Drive"). Because a disk array actually contains a number of physical disk drives, each of which can handle multiple requests, the queue depth for the disk array device has to be set to a value high enough to allow efficient use of all of the physical devices. For example, if `hdisk7` were an eight-disk non-IBM disk array, an appropriate change would be as follows:

```
# chdev -l hdisk7 -a q_type=simple -a queue_depth=24
```

If the disk array is attached through a SCSI-2 Fast/Wide SCSI adapter bus, it may also be necessary to change the outstanding-request limit for that bus.

Expanding the Configuration

Unfortunately, every performance-tuning effort ultimately does reach a point of diminishing returns. The question then becomes, "What hardware do I need, how much of it, and how do I make the best use of it?" That question is especially tricky with disk-limited workloads because of the large number of variables. Changes that might improve the performance of a disk-limited workload include:

- Adding disk drives and spreading the existing data across them. This divides the I/O load among more accessors.
- Acquiring faster disk drives to supplement or replace existing ones for high-usage data.
- Adding one or more disk adapters to attach the current and new disk drives.
- Adding RAM to the system and increasing the VMM's **minperm** and **maxperm** parameters to improve the in-memory caching of high-usage data.

For guidance more closely focused on your configuration and workload, you can use a measurement-driven simulator, such as BEST/1.

Using RAID

Redundant Array of Independent Disks (RAID) is a term used to describe the technique of improving data availability through the use of arrays of disks and various data-striping methodologies. Disk arrays are groups of disk drives that work together to achieve higher data-transfer and I/O rates than those provided by single large drives. An array is a set of multiple disk drives plus a specialized controller (an array controller) that keeps track of how data is distributed across the drives. Data for a particular file is written in segments to the different drives in the array rather than being written to a single drive.

Arrays can also provide data redundancy so that no data is lost if a single drive (physical disk) in the array should fail. Depending on the RAID level, data is either mirrored or striped.

Subarrays are contained within an array subsystem. Depending on how you configure it, an array subsystem can contain one or more sub-arrays, also referred to as Logical Units (LUN). Each LUN has its own characteristics (RAID level, logical block size and logical unit size, for example). From the operating system, each subarray is seen as a single hdisk with its own unique name.

RAID algorithms can be implemented as part of the operating system's file system software, or as part of a disk device driver (common for RAID 0 and RAID 1). These algorithms can be performed by a locally embedded processor on a hardware RAID adapter. Hardware RAID adapters generally provide better performance than software RAID because embedded processors offload the main system processor by performing the complex algorithms, sometimes employing specialized circuitry for data transfer and manipulation.

RAID Levels and Their Performance Implications

Each of the RAID levels supported by disk arrays uses a different method of writing data and hence provides different benefits.

RAID 0 - For Performance

RAID 0 is also known as *data striping*. It is well-suited for program libraries requiring rapid loading of large tables, or more generally, applications requiring fast access to read-only data, or fast writing. RAID 0 is only designed to increase performance; there is no redundancy, so any disk failures require reloading from backups. Select RAID Level 0 for applications that would benefit from the increased performance capabilities of this RAID Level. Never use this level for critical applications that require high availability.

RAID 1 - For Availability/Good Read Response Time

RAID 1 is also known as *disk mirroring*. It is most suited to applications that require high data availability, good read response times, and where cost is a secondary issue. The response time for writes can be somewhat slower than for a single disk, depending on the write policy; the writes can either be executed in parallel for speed or serially for safety. Select RAID Level 1 for applications with a high percentage of read operations and where the cost is not the major concern.

RAID 2 - Rarely Used

RAID 2 is rarely used. It implements the same process as RAID 3, but can utilize multiple disk drives for parity, while RAID 3 can use only one.

RAID 3 - For CAD/CAM, Sequential Access to Large Files

RAID 3 and RAID 2 are parallel process array mechanisms, where all drives in the array operate in unison. Similar to data striping, information to be written to disk is split into chunks (a fixed amount of data), and each chunk is written out to the same physical position on separate disks (in parallel). More advanced versions of RAID 2 and 3 synchronize the disk spindles so that the reads and writes can truly occur simultaneously (minimizing rotational latency buildups between disks). This architecture requires parity information to be written for each stripe of data; the difference between RAID 2 and RAID 3 is that RAID 2 can utilize multiple disk drives for parity, while RAID 3 can use only one. The LVM does not support RAID 3; therefore, a RAID 3 array must be used as a raw device from the host system.

Performance is very good for large amounts of data but poor for small requests because every drive is always involved, and there can be no overlapped or independent operation. It is well-suited for large data objects such as CAD/CAM or image files, or applications requiring sequential access to large data files. Select RAID 3 for applications that process large blocks of data. RAID 3 provides redundancy without the high overhead incurred by mirroring in RAID 1.

RAID 4 - Less Used (Parity Volume Bottleneck)

RAID 4 addresses some of the disadvantages of RAID 3 by using larger chunks of data and striping the data across all of the drives except the one reserved for parity. Write requests require a read/modify/update cycle that creates a bottleneck at the single parity drive. Therefore, RAID 4 is not used as often as RAID 5, which implements the same process, but without the parity volume bottleneck.

RAID 5 - High Availability and Fewer Writes Than Reads

RAID 5, as has been mentioned, is very similar to RAID 4. The difference is that the parity information is distributed across the same disks used for the data, thereby eliminating the bottleneck. Parity data is never stored on the same drive as the chunks that it protects. This means that concurrent read and write operations can now be performed, and there are performance increases due to the availability of an extra disk (the disk previously used for parity). There are other enhancements possible to further increase data transfer rates, such as caching simultaneous reads from the disks and transferring that information while reading the next blocks. This can generate data transfer rates at up to the adapter speed.

RAID 5 is best used in environments requiring high availability and fewer writes than reads. Select RAID level 5 for applications that manipulate small amounts of data, such as transaction processing applications.

RAID 6 - Seldom Used

RAID 6 is similar to RAID 5, but with additional parity information written that permits data recovery if two disk drives fail. Extra parity disk drives are required, and write performance is slower than a similar implementation of RAID 5.

RAID 7 - A Definition of 3rd Parties

The RAID 7 architecture gives data and parity the same privileges. The level 7 implementation allows each individual drive to access data as fast as possible. This is achieved by three features:

- Independent control and data paths for each I/O device/interface.
- Each device/interface is connected to a high-speed data bus that has a central cache capable of supporting multiple host I/O paths.
- A real time, process-oriented operating system is embedded into the disk drive array architecture. The embedded operating system "frees" the drives by allowing each drive head to move independently of the other disk drives. Also, the RAID 7 embedded operating system is enabled to handle a heterogeneous mix of disk drive types and sizes.

RAID 10 - RAID-0+1

RAID-0+1, also known in the industry as RAID 10, implements block interleave data striping and mirroring. RAID 10 is not formally recognized by the RAID Advisory Board (RAB), but, it is an industry standard term. In RAID 10, data is striped across multiple disk drives, and then those drives are mirrored to another set of drives.

The performance of RAID 10 is approximately the same as RAID 0 for sequential I/Os. RAID 10 provides an enhanced feature for disk mirroring that stripes data and copies the data across all the drives of the array. The first stripe is the data stripe; the second stripe is the mirror (copy) of the first data stripe, but it is shifted over one drive. Because the data is mirrored, the capacity of the logical drive is 50 percent of the physical capacity of the hard disk drives in the array.

Summary of RAID Levels

The advantages and disadvantages of the different RAID levels are summarized in the following table:

RAID Level	Availability	Capacity	Performance	Cost
------------	--------------	----------	-------------	------

0	none	100 percent	high	medium
1	mirroring	50 percent	medium/high	high
2/3	parity	80 percent	medium	medium
4/5/6/7	parity	80 percent	medium	medium
10	mirroring	50 percent	high	high

RAID Performance Summary

The most common RAID implementations are: 0, 1, 3 and 5. Levels 2, 4 and 6 have problems with performance and are functionally not better than the other ones. In most cases, RAID 5 is used instead of RAID 3 because of the bottleneck when using only one disk for parity.

RAID 0 and RAID 1 can be implemented with software support only. RAID 3, 5 and 7 require both hardware and software support (special RAID adapters or RAID array controllers).

For further information, see *Configuring and Implementing the IBM Fibre Channel RAID Storage Server*.

Using SSA

Serial Storage Architecture (SSA) is a high performance, serial interconnect technology used to connect disk devices and host adapters. SSA subsystems are built up of loops of adapters and disks. SSA is a serial link designed especially for low-cost, high-performance connection to disk drives. It is a two-signal connection (transmit and receive) providing full duplex communication. It uses a self-clocking code, which means that the data clock is recovered from the data signal itself rather than being transmitted as a separate signal.

Guidelines for Improving SSA Performance

Examine these guidelines in terms of your situation:

- Limit the number of disks per adapter so that the adapter is not flooded. With high throughputs using large block sizes, five to six disks can flood the adapter.
- Mirror across different adapters.
- The performance will be affected by the location of the logical volume on the disk. A contiguous, unfragmented partition in a logical volume will enhance performance.
- You can turn off mirror write consistency cache for logical volume mirroring, but doing so removes the guarantee of consistency of data in case of a crash. In this case, you would have to recopy all logical volumes to make sure they are consistent. However, the removal does provide a 20 percent plus enhancement in performance.
- For mirrored environments, make sure you are using the parallel scheduling policy.
- If any of the logical volume exists on more than one disk, stagger the partitions over the disks. This is automatically accomplished when the logical volume is created with the inter policy set to Maximum.
- Balance the I/Os across the loop; do not place all the workload on one half of the loop.
- In a multi-initiator environment, place the disks adjacent to the adapter that is using them.

For further information, see *Monitoring and Managing IBM SSA Disk Subsystems* and *A Practical Guide to Serial Storage Architecture for AIX*.

Additional information about IBM storage solutions can be found in *IBM Storage Solutions for e-business* and *Introduction to Storage Area Network*.

Using Fast Write Cache

Fast write cache (FWC) is an optional nonvolatile cache that provides redundancy with the standard adapter cache. The FWC tracks writes that have not been committed to disk.

FWC can significantly improve the response time for write operations. However, care must be taken not to flood the cache with write requests faster than the rate at which the cache can destage its data. It can also adversely affect the maximum I/O rate because additional processing is required in the adapter card to determine if the data that is being transferred is in the cache.

Fast write cache typically provides significant advantages in specialized workloads, for example, copying a database onto a new set of disks. If the fast write cache is spread over multiple adapters, this can multiply the benefit.

The FWC can also reduce JFS log bottlenecks because of three properties of the JFS log, as follows:

1. The JFS log is write-intensive. The FWC does not cache unmodified data.
2. The writes are small and frequent. Because the cache capacity is not enormous, it works best for high-rate small I/Os that are gathered together in the adapter into larger physical I/Os. Larger I/Os tend to have better performance because less disk rotations are normally needed to write the data.
3. Logs are not typically very large relative to the cache size, so the log does not tend to "wash" the cache frequently. Therefore, the log loses the benefit of rewriting over existing cached data. Although other array controllers with write caches have proven effective with logs, this article only discusses log performance with the FWC.

When single disk bandwidth becomes the limiting performance factor, one solution is to stripe several RAID 5 devices into a logical volume in conjunction with the FWC option of the SSA adapter. When the adapter is configured for RAID 5, writes equal to or larger than the stripe size bypass the cache. That is why 128 KB writes to a 2+p array with FWC are slower than 127 KB writes, and are equal to 128 KB writes to 2+p without the FWC. This is intended to keep bulk sequential I/O from "washing" the cache. The stripe size is 64 KB times the number of data disks in the RAID 5.

Chapter 9. Monitoring and Tuning Communications I/O Use

This chapter discusses several different communications protocols and ways to monitor and tune them. It contains the following major sections:

- UDP and TCP/IP Performance Overview
- Analyzing Network Performance
- Tuning TCP and UDP Performance
- Tuning mbuf Pool Performance
- Tuning Asynchronous Connections for High-Speed Transfers
- Tuning Name Resolution
- Improving telnetd/rlogind Performance
- Tuning the SP Network

UDP and TCP/IP Performance Overview

To understand the performance characteristics of UDP (user datagram protocol) and TCP/IP, you must first understand some of the underlying architecture. The following figure illustrates the structure that will be discussed in this chapter.

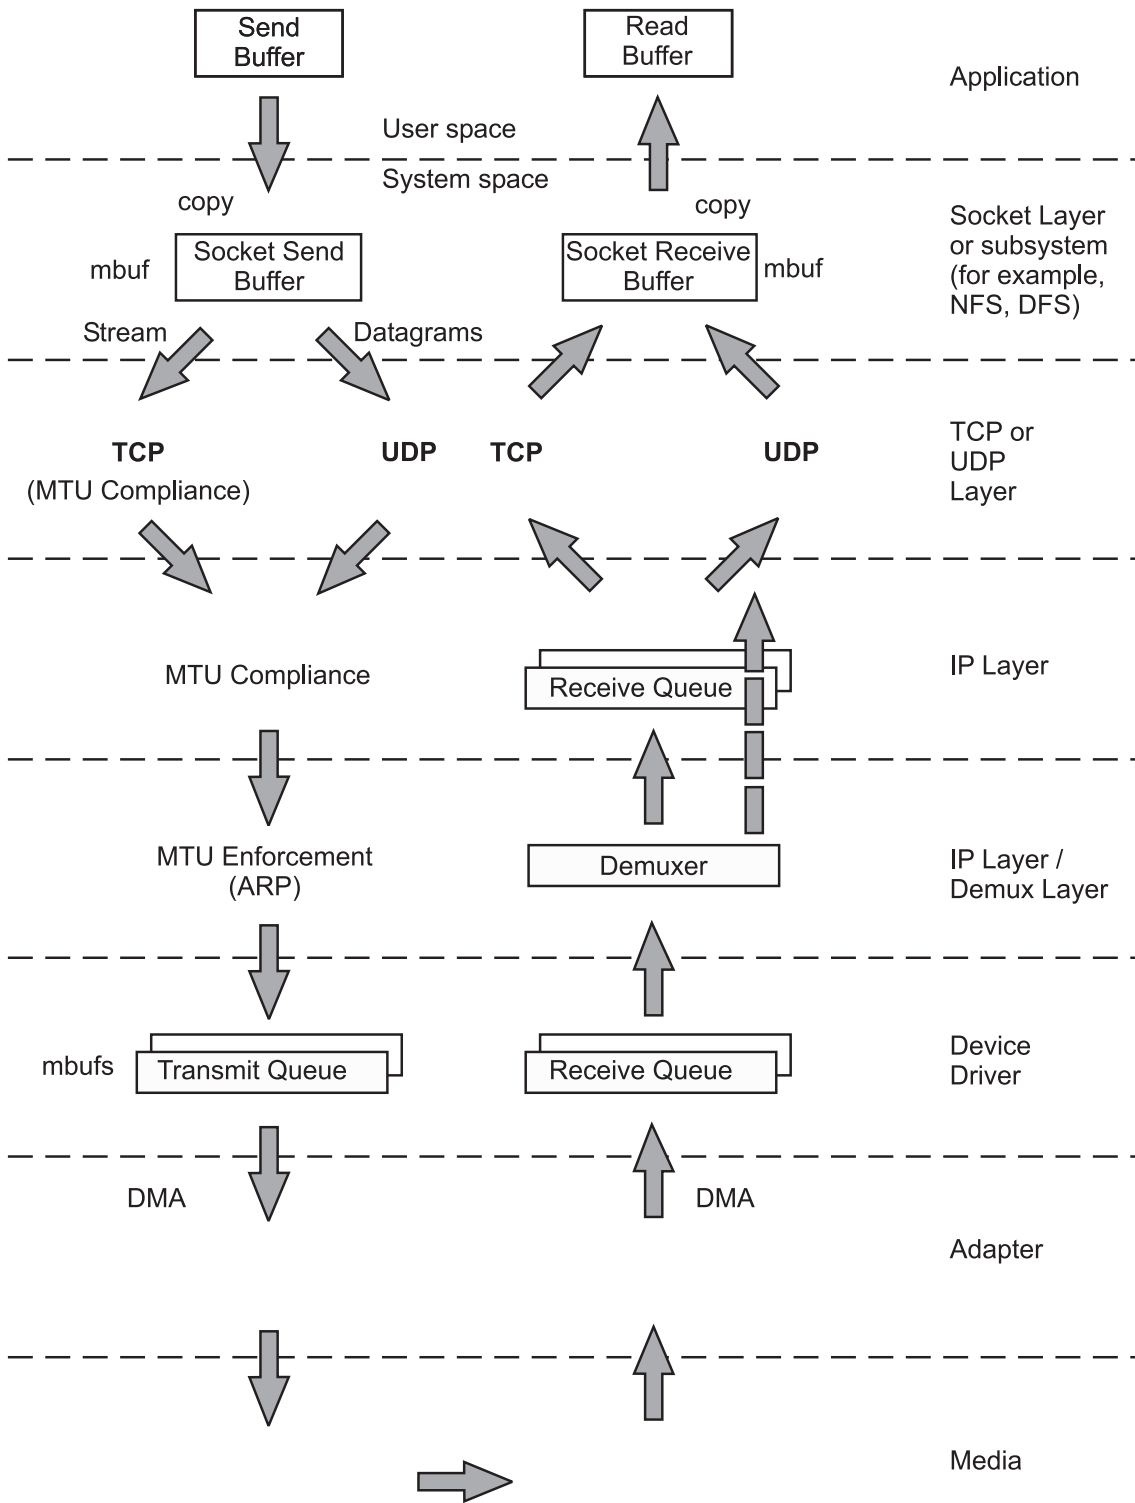

Figure 23. UDP and TCP/IP Data Flow. The figure shows the path of data from an application in one system to another application in a remote system. The steps of the data flow are described in the text immediately following the illustration.

Note: (ARP) address resolution protocol, see “Send Flow” on page 210.

The figure shows the path of data from an application in one system to another application in a remote system. The processing at each of the layers is discussed in this chapter, but key points are as follows:

- The application's write request causes the data to be copied from the application's working segment to the socket send buffer.
- The socket layer or subsystem calls UDP or TCP.
- The operating system has variable size clusters, so an optimum size is used when:
 - UDP copies and computes the checksum of the data into a socket buffer.
 - TCP copies the data to socket buffer.
- If the size of the data is larger than the maximum transfer unit (MTU) of the LAN, then:
 - TCP breaks the output into segments that comply with the MTU limit.
 - UDP leaves the breaking up of the output to the IP layer.
- If necessary, IP fragments the output into pieces that comply with the MTU, so that no outgoing packet exceeds the MTU limit.
- The packets are put on the device output queue and transmitted by the LAN adapter to the receiving system. If the output queue for the device overflows, the packet is discarded.
- Arriving packets are placed on the device driver's receive queue, and pass through the Interface layer to IP.
- If IP in the receiving system determines that IP in the sending system had fragmented a block of data, it coalesces the fragments into their original form and passes the data to TCP or UDP.
 - TCP reassembles the original segments and places the input in the socket receive buffer.
 - UDP passes the input on to the socket receive buffer. If the input socket (**udp_recvspace**) limit is reached, the packet is discarded.
- When the application makes a read request, the appropriate data is copied from the socket receive buffer in kernel memory into the buffer in the application's buffer.

Communication Subsystem Memory (mbuf) Management

To avoid fragmentation of kernel memory and the overhead of numerous calls to the **xmalloc()** subroutine, the various layers of the communication subsystem share common buffer pools. The mbuf management facility controls different buffer sizes. The pools consist of pinned pieces of kernel virtual memory; this means that they always reside in physical memory and are never paged out. The result is that the real memory available for paging in application programs and data has been decreased by the amount that the mbuf pools have been increased.

In addition to avoiding duplication, sharing the mbuf and cluster pools allows the various layers to pass pointers to one another, reducing mbuf management calls and copying of data.

For additional details, see Tuning mbuf Pool Performance.

Socket Layer

Sockets provide the application program interface (API) to the communication subsystem. Several types of sockets provide various levels of service by using different communication protocols. Sockets of type **SOCK_DGRAM** use the UDP protocol. Sockets of type **SOCK_STREAM** use the TCP protocol.

The processes of opening, reading, and writing to sockets are similar to those for manipulating files.

The sizes of the buffers in system virtual memory (that is, the total number of bytes from the mbuf pools) that are used by the input and output sides of each socket are limited by system-wide default values (which can be overridden for a given socket by a call to the **setsockopt()** subroutine):

udp_sendspace and udp_recvspace

Buffer sizes for datagram sockets in bytes. The defaults are 9216 and 41920, respectively.

tcp_sendspace and tcp_recvspace

Buffer sizes for stream sockets in bytes. The defaults for both values are 16384. With AIX 4.3.3 and later, these two parameters can also be set using ISNO (see Interface-Specific Network Options (ISNO)).

Use the following to display these values:

```
# no -a
```

A root user can set these values as follows:

```
# no -o udp_sendspace=NewValue
```

The *NewValue* parameter must be less than or equal to the **sb_max** parameter, which controls the maximum amount of space that can be used by a socket's send or receive buffer. The default value of the **sb_max** parameter depends on the operating system version and amount of real memory. The **sb_max** value is displayed with the command **no -a** and set with the **no** command, as follows:

```
# no -o sb_max=NewLimit
```

Note: Socket send or receive buffer sizes are limited to no more than **sb_max** bytes, because **sb_max** is a ceiling on buffer space consumption. The two quantities are not measured in the same way, however. The socket buffer size limits the amount of data that can be held in the socket buffers. The **sb_max** value limits the number of bytes of mbufs that can be in the socket buffer at any given time. In an Ethernet environment, for example, each 2048-byte mbuf cluster might hold just 1500 bytes of data. In that case, **sb_max** would have to be 1.37 times larger than the specified socket buffer size to allow the buffer to reach its specified capacity. The guideline is to set **sb_max** to at least twice the size of the largest socket buffer.

Send Flow

As an application writes to a socket, the socket layer calls the transport layer (either TCP or UDP), which copies the data from user space into the socket send buffer in kernel space. Depending on the amount of data being copied into the socket send buffer, the code puts the data into either mbufs or clusters.

Receive Flow

On the receive side, an application opens a socket and attempts to read data from it. If there is no data in the socket receive buffer, the socket layer causes the application thread to go to the sleep state (blocking) until data arrives. When data arrives, it is put on the receive socket buffer queue and the application thread is made dispatchable. The data is then copied into the application's buffer in user space, the mbuf chain is freed, and control is returned to the application.

Socket Creation

In AIX 4.3.1 and later, the **sockthresh** value determines how much of the system's network memory can be used before socket creation is disallowed. The value of **sockthresh** is given as a percentage of **thewall**. It has a default of 85 percent and can be set to any value from 1 to 100. However, **sockthresh** cannot be set to a value lower than the amount of memory currently in use.

The **sockthresh** option is intended to prevent situations where many connections are opened until all the network memory on the machine is used. This leaves no memory for other operations, and the machine hangs and must be rebooted to recover. Use **sockthresh** to set the point at which new sockets should not be allowed. Calls to the **socket()** and **socketpair()** subroutines will fail with an error of ENOBUFS, and incoming connection requests will be silently discarded. This allows the remaining network memory to be used by existing connections and prevents the machine from hanging.

The **netstat -m** statistic sockets not created because sockthresh was reached is incremented each time a socket creation fails because the amount of network memory already in use is over the **sockthresh** limit.

Use the following to display the **sockthresh** value:

```
# no -o sockthresh
```

A root user can set the value as follows:

```
# no -o sockthresh=NewValue
```

The default value can be set as follows:

```
# no -d sockthresh
```

Ephemeral Ports

When an application requests that the system assign the port (application is not requesting a specific port number), this is called an *ephemeral port*. Prior to AIX 4.3.1, the ephemeral port range was from 1024 to 5000. Starting with AIX 4.3.1, the default starting ephemeral port number is 32768, and the default largest ephemeral port number is 65535.

Using the **no** command, these values can be tuned with the **tcp_ephemeral_low** and **tcp_ephemeral_high** parameters. The maximum range would be to set **tcp_ephemeral_low** to 1024 and **tcp_ephemeral_high** to 65535. UDP ports have the same tunable parameters available through **udp_ephemeral_low** and **udp_ephemeral_high** (defaults are identical).

Relative Level of Function in UDP and TCP

The following two sections contain descriptions of the function of UDP and TCP. To facilitate comparison of UDP and TCP, both descriptions are divided into subsections on connection, error detection, error recovery, flow control, data size, and MTU handling.

UDP Layer

UDP provides a low-cost protocol for applications that have the facilities to deal with communication failures. UDP is most suitable for *request-response* applications. Because such an application has to handle a failure to respond anyway, it is little additional effort to handle communication error as one of the causes of failure to respond. For this reason, and because of its low overhead, subsystems such as NFS, ONC RPC, DCE RPC, and DFS use UDP.

Features of the UDP layer are as follows:

Connection

None. UDP is essentially a stateless protocol. Each request received from the caller is handled independently of those that precede or follow it. (If the **connect()** subroutine is called for a datagram socket, the information about the destination is considered a hint to cache the resolved address for future use. It does not actually bind the socket to that address or affect UDP on the receiving system.)

Error detection

Checksum creation and verification. The sending UDP builds the checksum and the receiving UDP checks it. If the check fails, the packet is dropped.

Error recovery

None. UDP does not acknowledge receipt of packets, nor does it detect their loss in transmission or through buffer-pool overflow. Consequently, UDP never retransmits a packet. Recovery must be performed by the application.

Flow control

None. When UDP is asked to send, it sends the packet to IP. When a packet arrives from IP, it is placed in the socket-receive buffer. If either the device driver/adaptor buffer queue or the socket-receive buffer is full when the packet arrives, the packet is dropped without an error indication. The application or subsystem that sent the packet must detect the failure by timeout or sequence and retry the transmission. Various statistics show counts of discarded packets (see the **netstat -s** and **netstat -D** commands in The netstat Command).

Data size

Must fit in one buffer. This means that the buffer pools on both sides of UDP must have buffer sizes that are adequate for the applications' requirements. The maximum size of a UDP packet is

64 KB. Of course, an application that builds large blocks can break them into multiple datagrams itself (for example, DCE), but it is simpler to use TCP.

MTU handling

None. Dealing with data larger than the maximum transfer unit (MTU) size for the interface is left to IP. If IP has to fragment the data to make it fit the MTU, loss of one of the fragments becomes an error that the application or subsystem must deal with timeout and retransmit logic.

Send Flow: If **udp_sendspace** is large enough to hold the datagram, the application's data is copied into mbufs in kernel memory. If the datagram is larger than **udp_sendspace**, an error is returned to the application.

The operating system chooses optimum size buffers from a power of 2 size buffer. For example, a write of 8704 bytes is copied into two clusters, a 8192-byte and a 512-byte cluster. UDP adds the UDP header (in the same mbuf, if possible), checksums the data, and calls the IP **ip_output()** routine.

Receive Flow: UDP verifies the checksum and queues the data onto the proper socket. If the **udp_recvspace** limit is exceeded, the packet is discarded. A count of these discards is reported by the **netstat -s** command under **udp**: as **socket buffer overflows**. If the application is waiting for a receive or read on the socket, it is put on the run queue. This causes the receive to copy the datagram into the user's address space and release the mbufs, and the receive is complete. Usually, the receiver responds to the sender to acknowledge the receipt and also return a response message.

In AIX 4.1.1 and later, UDP checksums the data "on the fly" when it copies it into the kernel mbuf. When receiving, this same optimization can be done, but the application must enable it with the **SO_CKSUMRECV** option on a **setsockopt()** call. Applications that receive large UDP buffers should program to use this option for better performance.

TCP Layer

TCP provides a reliable transmission protocol. TCP is most suitable for applications that, at least for periods of time, are mostly output or mostly input. With TCP ensuring that packets reach their destination, the application is freed from error detection and recovery responsibilities. Applications that use TCP transport include **ftp**, **rnp**, and **telnet**. DCE can use TCP if it is configured to use a connection-oriented protocol.

Features of the TCP layer are as follows:

Connection

Explicit. The instance of TCP that receives the connection request from an application (call it the *initiator, sender, or transmitter*) establishes a session with its counterpart on the other system, which you will call the *listener, or receiver*. All exchanges of data and control packets are within the context of that session.

Error detection

Checksum creation and verification. The sending TCP builds the checksum and the receiving TCP checks it. If checksum verification fails, the receiver does not acknowledge receipt of the packet. Some PCI adapters now have TCP checksum offload. For example, the Gigabit Ethernet adapter for transmits and receives, and the ATM 155 adapter for transmits. The default is set to on. The transmit can be disabled with the **ifconfig** command and the **checksum_offload** parameter, while the receive requires a **chdev** command to set **cx_checksum=no**.

Error recovery

Full. TCP detects checksum failures and loss of a packet or fragment through timeout. In error situations TCP retransmits the data until it is received correctly (or notifies the application of an unrecoverable error).

Flow control

Enforced. TCP uses a discipline called a *sliding window* to ensure delivery to the receiving application. The sliding window concept is illustrated in the following figure. (The records shown in

the figure are for clarity only. TCP processes data as a stream of bytes and does not keep track of record boundaries, which are application-defined.)

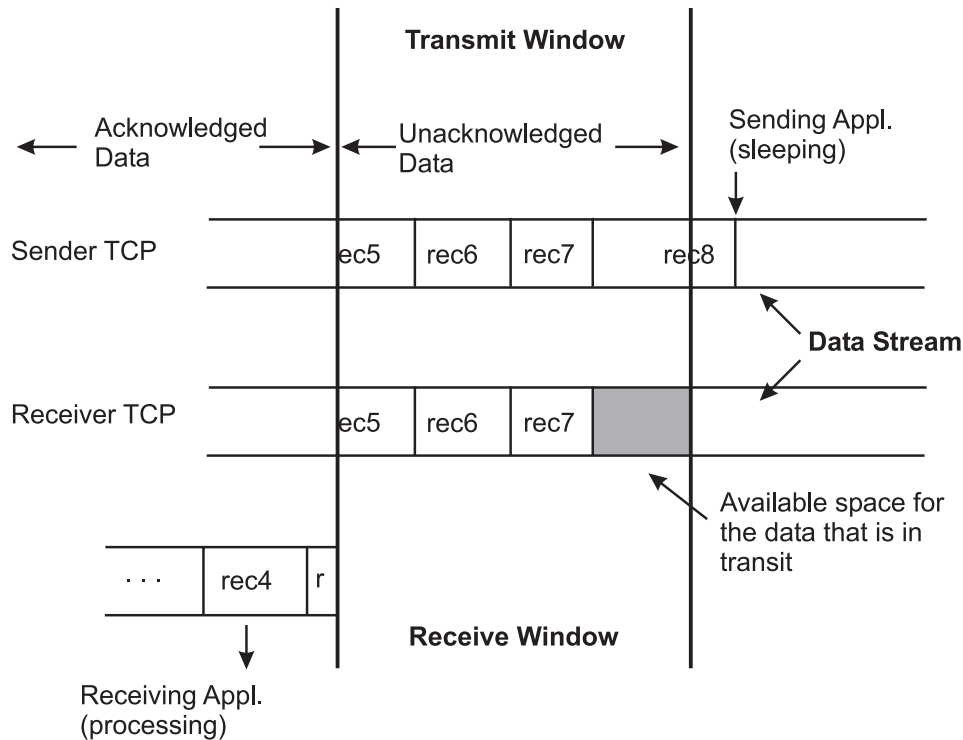

Figure 24. TCP Sliding Window. This illustration depicts the TCP Sliding Window. A full description is in the text immediately following the figure.

In this figure, the sending application is sleeping because it has attempted to write data that would cause TCP to exceed the send socket buffer space (that is, **tcp_sendspace**). The sending TCP still has the last part of **rec5**, all of **rec6** and **rec7**, and the beginning of **rec8**. The receiving TCP has not yet received the last part of **rec7** or any of **rec8**. The receiving application got **rec4** and the beginning of **rec5** when it last read the socket, and it is now processing that data. When the receiving application next reads the socket, it will receive (assuming a large enough read), the rest of **rec5**, **rec6**, and as much of **rec7** and **rec8** as has arrived by that time.

After the next read, the following occur:

- The receiving TCP will be able to acknowledge that data
- The sending TCP will be able to discard the data
- The pending write will complete

The sending application will wake up. To avoid excessive LAN traffic when the application is reading in tiny amounts, TCP delays acknowledgment until the receiving application has read a total amount of data that is at least half the receive window size or twice the maximum segment size.

If there is no data to send back, the receiver will delay up to 200 ms and then send the ACK. The delay time can be tuned by a new **no** parameter called **fasttimeo**. The default value is 200 ms, and the range of values can be between 50 ms and 200 ms. Reducing this value may enhance performance of request/response type of applications.

Note: When using TCP to exchange request/response messages, the application must use the **setsockopt()** subroutine to turn on the **TCP_NODELAY** option. This causes TCP to send

the message immediately (within the constraints of the sliding window), even though it is less than MTU-size. Otherwise, TCP would wait for up to 200 milliseconds for more data to send before transmitting the message. Starting with AIX 4.3.3 the **tcp_nodelay** parameter can be set with the **ifconfig** or **chdev** command to set TCP_NODELAY on TCP sockets (see Interface-Specific Network Options (ISNO)).

In the course of establishing a session, the initiator and the listener converse to determine the receive space for each end point. The size defines the size of the receive window. As data is written to the socket, it is moved into the sender's buffer. When the receiver indicates that it has space available, the sender transmits enough data to fill that space (assuming that it contains that much data). When the receiving application reads from the socket, the receiving socket returns as much data as it has in its receive socket buffer. TCP then informs the sender that the data has been successfully delivered by sending a packet to advance the receiver window. Only then does the sending TCP discard the data from its own buffer, effectively moving the window to the right by the amount of data delivered. If the window is full because the receiving application has fallen behind, the sending thread will be blocked (or receive a specific errno) when it tries to write to the socket.

The value of **tcp_recvspace** and **tcp_sendspace** are independent. The **tcp_sendspace** controls the buffering in the kernel of the sender. The **tcp_recvspace** controls the receiver space and translates into TCP's receive window.

If the **rfc1323** parameter is 1, the maximum TCP window size is 4 GB (instead of 64 KB).

Data size

Indefinite. TCP does not process records or blocks; it processes a stream of bytes. If a send buffer is larger than the receiver can handle, it is segmented into MTU-size packets. Because it handles shortages of buffer space under the covers, TCP does not guarantee that the number and size of data receives will be the same as the number and size of sends. It is the responsibility of the two sides of the application to identify record or block boundaries, if any, within the stream of data.

MTU handling

Handled by segmentation in TCP. When the connection is established, the initiator and the listener negotiate a maximum segment size (MSS) to be used. The MSS is typically smaller than the MTU (see Tuning TCP Maximum Segment Size). If the output packet size exceeds the MSS, TCP does the segmentation, thus making fragmentation in IP unnecessary. The receiving TCP typically puts the segments on the socket receive queue as they arrive. If the receiving TCP detects the loss of a segment, it withholds acknowledgment and holds back the succeeding segments until the missing segment has been received successfully.

The additional operations performed by TCP to ensure a reliable connection result in about 5 to 10 percent higher processor cost than in UDP.

Send Flow: When the TCP layer receives a write request from the socket layer, it allocates a new mbuf for its header information and copies the data in the socket-send buffer either into the TCP-header mbuf, if there is room, or into a newly allocated mbuf chain. If the data being copied is in clusters, the data is not actually copied into new clusters. Instead, a pointer field in the new mbuf header (this header is part of the mbuf structure and is unrelated to the TCP header) is set to point to the clusters containing the data, thereby avoiding the overhead of one or more 4 KB copies. TCP then checksums the data (unless it is offloaded by certain PCI adapters), updates its various state variables, which are used for flow control and other services, and finally calls the IP layer with the header mbuf now linked to the new mbuf chain.

Receive Flow: When the TCP input routine receives input data from IP, the following occur:

- It checksums the TCP header and data for corruption detection (unless it is offloaded by certain PCI adapters)

- Determines which connection this data is for
- Removes its header information
- Links the mbuf chain onto the socket-receive buffer associated with this connection
- Uses a socket service to wake up the application (if it is sleeping as described earlier)

IP Layer

The Internet Protocol provides a basic datagram service to the higher layers. If it is given a packet larger than the MTU of the interface, it fragments the packet and sends the fragments to the receiving system, which reassembles them into the original packet. If one of the fragments is lost in transmission, the incomplete packet is ultimately discarded by the receiver. MTU path discovery can be enabled as described in Tuning TCP Maximum Segment Size.

The length of time IP waits for a missing fragment is controlled by the **ipfragttl** parameter, which is set and displayed with the **no** command.

Following are some default values and value ranges for different network types:

Network Type	Default (bytes)	Range (bytes)
X.25	576	60-2058
SLIP	1006	60-4096
Standard Ethernet	1500	60 - 1500
IEEE 802.3 Ethernet	1492	60 - 1492
Gigabit Ethernet	9000 (Jumbo Frames)	N/A
Token-Ring 4 Mbps	1492	60 - 4096
Token-Ring 16 Mbps	1492	60 - 17800
FDDI	4352	1 - 4352
SLA (socc)	61428	1 - 61428
ATM	9180	1 - 65527
HIPPI	65536	60 - 65536
SP Switch	65520	1 - 65520

Note: In general, you can increase the transmit and receive queues. This requires some memory, but avoids some problems. See Adapter Transmit and Receive Queue Tuning.

Send Flow

When the IP output routine receives a packet from UDP or TCP, it identifies the interface to which the mbuf chain should be sent, updates and checksums the IP part of the header, and passes the packet to the interface (IF) layer.

IP determines the proper device driver and adapter to use, based on the network number. The driver interface table defines the maximum MTU for this network. If the datagram is less than the MTU size, IP adds the IP header in the existing mbuf, checksums the IP header, and calls the driver to send the frame. If the driver send queue is full, an EAGAIN error is returned to IP, which returns it to UDP, which returns it to the sending application. The sender should delay and try again.

If the datagram is larger than the MTU size (which only occurs in UDP), IP fragments the datagram into MTU-size fragments, appends a IP header (in an mbuf) to each, and calls the driver once for each fragment frame. If the driver's send queue is full, an EAGAIN error is returned to IP. IP discards all

remaining unsend fragments associated with this datagram and returns EAGAIN to UDP. UDP returns EAGAIN the sending application. Since IP and UDP do not queue messages, it is up to the application to delay and try the send again.

Receive Flow

In AIX Version 4, in general, interfaces do not perform queuing and directly call the IP input queue routine to process the packet; the loopback interface will still perform queuing. In the case of queuing, the demux layer places incoming packets on this queue. If the queue is full, packets are dropped and never reach the application. If packets are dropped at the IP layer, a statistic called `ipintrq overflows` in the output of the `netstat -s` command is incremented. If this statistic increases in value, then use the `no` command to tune the `ipqmaxlen` tunable.

In AIX Version 4, the demux layer (formerly called the *IF layer*) calls IP on the interrupt thread. IP checks the IP header checksum to make sure the header was not corrupted and determines if the packet is for this system. If so, and the frame is not a fragment, IP passes the mbuf chain to the TCP or UDP input routine.

If the received frame is a fragment of a larger datagram (which only occurs in UDP), IP retains the frame. When the other fragments arrive, they are merged into a logical datagram and given to UDP when the datagram is complete. IP holds the fragments of an incomplete datagram until the `ipfragttl` time (as specified by the `no` command) expires. The default `ipfragttl` time is 30 seconds (an `ipfragttl` value of 60). If any fragments are lost due to problems such as network errors, lack of mbufs, or transmit queue overruns, IP never receives them. When `ipfragttl` expires, IP discards the fragments it did receive. This is reported as a result from the `netstat -s` command. Under `ip:`, see fragments dropped after timeout.

Demux Layer

The interface layer (IF) is used on output and is the same level as the demux layer (used for input) in AIX Version 4. It places transmit requests on to a transmit queue, where the requests are then serviced by the network interface device driver. The size of the transmit queue is tunable, as described in Adapter Transmit and Receive Queue Tuning.

Send Flow

When the demux layer receives a packet from IP, it attaches the link-layer header information to the beginning of the packet, checks the format of the mbufs to make sure they conform to the device driver's input specifications, and then calls the device driver write routine.

The address resolution protocol (ARP) is also handled in this layer. ARP translates a 32-bit Internet Protocol (IP) address into a 48-bit hardware address.

Receive Flow

In AIX Version 4, when the demux layer receives a packet from the device driver, it calls IP on the interrupt thread to perform IP input processing.

If the dog threads are enabled (see Enabling Thread Usage on LAN Adapters (dog threads)), the incoming packet will be queued to the thread and the thread will handle calling IP, TCP, and the socket code.

LAN Adapters and Device Drivers

The operating system environment supports many different kinds of LAN adapters. You can choose from a wide variety of network interfaces. As the following table shows, as the speed of these networks varies, so does the performance.

Name	Speed
Ethernet (en)	10 Mbit/sec - Gigabits/sec
IEEE 802.3 (et)	10 Mbit/sec - Gigabits/sec
Token-Ring (tr)	4 or 16 Mbit/sec

X.25 protocol (xt)	64 Kb/sec
Serial Line Internet Protocol, SLIP (sl)	64 Kb/sec
loopback (lo)	N/A
FDDI (fi)	100 Mbit/sec
SOCC (so)	220 Mbit/sec
ATM (at)	100s Mbit/sec (many Gb/sec)

Refer to the *PCI Adapter Placement Reference* and *RS/6000 Systems Handbook* for slot placement guidelines and limitations that may exist on the number of adapters that can be supported for connectivity and the number that can be supported for maximum performance.

Several PCI machines have secondary PCI buses bridged onto a primary PCI bus. Some medium- to high-speed adapters perform slower on these secondary bus slots and some adapters are not recommended to be used in these slots. Machines with some secondary PCI slots include E30, F40, and SP 332 MHz SMP-wide nodes.

The adapters differ, not only in the communications protocol and transmission medium they support, but also in their interface to the I/O bus and the processor. Similarly, the device drivers vary in the technique used to convey the data between memory and the adapter. The following description of send and receive flow applies to most adapters and device drivers, but details vary.

Send Flow

At the device-driver layer, the mbuf chain containing the packet is enqueued on the transmit queue. The maximum total number of output buffers that can be queued is controlled by the system parameter **xmt_que_size**. In some cases, the data is copied into driver-owned DMA buffers. The adapter is then signaled to start DMA operations.

At this point, control returns up the path to the TCP or UDP output routine, which continues sending as long as it has data to send. When all data has been sent, control returns to the application, which then runs asynchronously while the adapter transmits data. Device driver dependent, when the adapter has completed transmission, it sends an interrupt to the system. When the interrupt is handled, the device-interrupt routines are called to adjust the transmit queues and free the mbufs that held the transmitted data.

Receive Flow

When frames are received by an adapter, they are transferred from the adapter into a driver-managed receive queue. The receive queue can consist of mbufs or the device driver can manage a separate pool of buffers for the device. In either case, the data is in an mbuf chain when it is passed from the device driver to the demux layer.

Some drivers receive frames through Direct Memory Access (DMA) into a pinned area of memory and then allocate mbufs and copy the data into them. Drivers/adapters that receive large-MTU frames may have the frames accessed directly into cluster mbufs. The driver transfers the frame to the correct network protocol (IP in this example) by calling a demultiplexing function that identifies the packet type and puts the mbuf containing the buffer on the input queue for that network protocol. If no mbufs are available or if the higher-level input queue is full, the incoming frames are discarded.

Analyzing Network Performance

When performance problems arise, your system might be totally innocent, while the real culprit is buildings away. An easy way to tell if the network is affecting overall performance is to compare those operations that involve the network with those that do not. If you are running a program that does a considerable amount of remote reads and writes and it is running slowly, but everything else seems to be running as usual, then it is probably a network problem. Some of the potential network bottlenecks can be caused by the following:

- Client-network interface
- Network bandwidth
- Network topology
- Server network interface
- Server CPU load
- Server memory usage
- Server bandwidth
- Inefficient configuration

Several tools can measure network statistics and give a variety of information, but only part of this information is related to performance tuning.

To enhance performance, you can use the **no** (network options) command and the **nfs** command for tuning NFS options. You can also use the **chdev** and **ifconfig** commands to change system and network parameters.

The ping Command

The **ping** command is useful for the following:

- Determining the status of the network and various foreign hosts.
- Tracking and isolating hardware and software problems.
- Testing, measuring, and managing networks.

Some **ping** command options relevant to performance tuning are as follows:

- c** Specifies the number of packets. This option is useful when you get an IP trace log. You can capture a minimum of **ping** packets.
- s** Specifies the length of packets. You can use this option to check fragmentation and reassembly.
- f** Sends the packets at 10 ms intervals or immediately after each response. Only the root user can use this option.

If you need to load your network or systems, the **-f** option is convenient. For example, if you suspect that your problem is caused by a heavy load, load your environment intentionally to confirm your suspicion. Open several **aixterm** windows and run the **ping -f** command in each window. Your Ethernet utilization quickly gets to around 100 percent. The following is an example:

```
# date ; ping -c 1000 -f wave ; date
Fri Jul 23 11:52:39 CDT 1999
PING wave.austin.ibm.com: (9.53.153.120): 56 data bytes
.
----wave.austin.ibm.com PING Statistics----
1000 packets transmitted, 1000 packets received, 0% packet loss
round-trip min/avg/max = 1/1/23 ms
Fri Jul 23 11:52:42 CDT 1999
```

Note: This command can be very hard on a network and should be used with caution. Flood-pinging can only be performed by the root user.

In this example, 1000 packets were sent for 3 seconds. Be aware that this command uses IP and Internet Control Message Protocol (ICMP) protocol and therefore, no transport protocol (UDP/TCP) and application activities are involved. The measured data, such as round-trip time, does not reflect the total performance characteristics.

When you try to send a flood of packets to your destination, consider several points:

- Sending packets puts a load on your system.
- Use the **netstat -i** command to monitor the status of your network interface during the experiment. You may find that the system is dropping packets during a send by looking at the 0errs output.
- You should also monitor other resources, such as mbufs and send/receive queue. It can be difficult to place a heavy load onto the destination system. Your system might be overloaded before the other system is.
- Consider the relativity of the results. If you want to monitor or test just one destination system, do the same experiment on some other systems for comparison, because your network or router might have a problem.

The ftp Command

You can use the **ftp** command to send a very large file by using **/dev/zero** as input and **/dev/null** as output. This allows you to transfer a large file without involving disks (which might be a bottleneck) and without having to cache the entire file in memory.

Use the following **ftp** subcommands (change count to increase or decrease the number of blocks read by the **dd** command):

```
> bin
> put "|dd if=/dev/zero bs=32k count=10000" /dev/null
```

Remember, if you change the TCP send or receive space parameters, then for the **ftp** command, you must refresh the **inetd** daemon with the **refresh -s inetd** command.

Make sure that **tcp_sendspace** and **tcp_recvspace** are at least 65535 for the Gigabit Ethernet "jumbo frames" and for the ATM with MTU 9180 or larger to get good performance due to larger MTU size.

An example to set the parameters is as follows:

```
# no -o tcp_sendspace=65535
# no -o tcp_recvspace=65535
# refresh -s inetd
0513-095 The request for subsystem refresh was completed successfully.
```

The **ftp** subcommands are as follows:

```
ftp> bin
200 Type set to I.
ftp> put "|dd if=/dev/zero bs=32k count=10000" /dev/null
200 PORT command successful.
150 Opening data connection for /dev/null.
10000+0 records in
10000+0 records out
226 Transfer complete.
327680000 bytes sent in 8.932 seconds (3.583e+04 Kbytes/s)
local: |dd if=/dev/zero bs=32k count=10000 remote: /dev/null
ftp> quit
221 Goodbye.
```

The netstat Command

The **netstat** command is used to show network status. Traditionally, it is used more for problem determination than for performance measurement. However, the **netstat** command can be used to determine the amount of traffic on the network to ascertain whether performance problems are due to network congestion.

The **netstat** command displays information regarding traffic on the configured network interfaces, such as the following:

- The address of any protocol control blocks associated with the sockets and the state of all sockets
- The number of packets received, transmitted, and dropped in the communications subsystem
- Cumulative statistics per interface
- Routes and their status

Using the netstat Command

The **netstat** command displays the contents of various network-related data structures for active connections. In this chapter, only the options and output fields that are relevant for network performance determinations are discussed. For all other options and columns, see the *AIX 5L Version 5.1 Commands Reference*.

netstat -i: Shows the state of all configured interfaces.

The following example shows the statistics for a workstation with an integrated Ethernet and a Token-Ring adapter:

```
# netstat -i
Name Mtu Network Address Ipkts Ierrs Opkts Oerrs Coll
lo0 16896 <Link> 144834 0 144946 0 0
lo0 16896 127 localhost 144834 0 144946 0 0
tr0 1492 <Link>10.0.5a.4f.3f.61 658339 0 247355 0 0
tr0 1492 9.3.1 ah6000d 658339 0 247355 0 0
en0 1500 <Link>8.0.5a.d.a2.d5 0 0 112 0 0
en0 1500 1.2.3 1.2.3.4 0 0 112 0 0
```

The count values are summarized since system startup.

Name Interface name.

Mtu Maximum transmission unit. The maximum size of packets in bytes that are transmitted using the interface.

Ipkts Total number of packets received.

Ierrs Total number of input errors. For example, malformed packets, checksum errors, or insufficient buffer space in the device driver.

Opkts Total number of packets transmitted.

Oerrs Total number of output errors. For example, a fault in the local host connection or adapter output queue overrun.

Coll Number of packet collisions detected.

Note: The **netstat -i** command does not support the collision count for Ethernet interfaces (see The **netstat** Command for Ethernet statistics).

Following are some tuning guidelines:

- If the number of errors during input packets is greater than 1 percent of the total number of input packets (from the command **netstat -i**); that is,

$$Ierrs > 0.01 \times Ipkts$$

Then run the **netstat -m** command to check for a lack of memory.

- If the number of errors during output packets is greater than 1 percent of the total number of output packets (from the command **netstat -i**); that is,

```
Oerrs > 0.01 x Opkts
```

Then increase the send queue size (**xmt_que_size**) for that interface. The size of the **xmt_que_size** could be checked with the following command:

```
# lsattr -El adapter
```

- If the collision rate is greater than 10 percent, that is,

```
Coll / Opkts > 0.1
```

Then there is a high network utilization, and a reorganization or partitioning may be necessary. Use the **netstat -v** or **entstat** command to determine the collision rate.

netstat -i -Z: This function of the **netstat** command clears all the statistic counters for the **netstat -i** command to zero.

netstat -I interface interval: Displays the statistics for the specified interface. It offers information similar to the **netstat -i** command for the specified interface and reports it for a given time interval. For example:

```
# netstat -I en0 1
  input      (en0)      output      input      (Total)      output
  packets  errs  packets  errs  colls  packets  errs  packets  errs  colls
    0      0      27      0      0      799655   0    390669   0      0
    0      0      0      0      0         2      0         0      0      0
    0      0      0      0      0         1      0         0      0      0
    0      0      0      0      0        78      0        254    0      0
    0      0      0      0      0       200     0         62     0      0
    0      0      1      0      0         0      0         2      0      0
```

The previous example shows the **netstat -I** command output for the **en0** interface. Two reports are generated side by side, one for the specified interface and one for all available interfaces (Total). The fields are similar to the ones in the **netstat -i** example, input packets = **Ipkts**, input errs = **Ierrs** and so on.

netstat -m: Displays the statistics recorded by the mbuf memory-management routines. The most useful statistics in the output of the **netstat -m** command are the counters that show the requests for mbufs denied and non-zero values in the failed column. If the requests for mbufs denied is not displayed, then this must be an SMP system running operating system version 4.3.2 or later; for performance reasons, global statistics are turned off by default. To enable the global statistics, set the **no** parameter **extended_netstats** to 1. This can be done by changing the **/etc/rc.net** file and rebooting the system.

The following example shows the first part of the **netstat -m** output with **extended_netstats** set to 1:

```
# netstat -m
29 mbufs in use:
16 mbuf cluster pages in use
71 Kbytes allocated to mbufs
0 requests for mbufs denied
0 calls to protocol drain routines
```

Kernel malloc statistics:

```
***** CPU 0 *****
By size      inuse      calls failed   delayed   free      hiwat      freed

By type inuse calls failed delayed memuse memmax mapb

Streams mblk statistic failures:

0 high priority mblk failures

0 medium priority mblk failures

0 low priority mblk failures

If global statistics are not on and you want to determine the total number of requests for mbufs denied, add up the values under the `failed` columns for each CPU. If the `netstat -m` command indicates that requests for mbufs or clusters have failed or been denied, then you may want to increase the value of `thewall` by using the `no -o thewall=NewValue` command. See Overview of the mbuf Management Facility for additional details about the use of `thewall` and `maxmbuf`.

Beginning with AIX 4.3.3, a `delayed` column was added. If the requester of an mbuf specified the `M_WAIT` flag, then if an mbuf was not available, the thread is put to sleep until an mbuf is freed and can be used by this thread. The failed counter is not incremented in this case; instead, the `delayed` column will be incremented. Prior to AIX 4.3.3, the failed counter was also not incremented, but there was no `delayed` column.

Also, if the currently allocated amount of network memory is within 85 percent of `thewall`, you may want to increase `thewall`. If the value of `thewall` is increased, use the `vmstat` command to monitor total memory use to determine if the increase has had a negative impact on overall memory performance.

If buffers are not available when a request is received, the request is most likely lost (to see if the adapter actually dropped a package, see Adapter Statistics). Keep in mind that if the requester of the mbuf specified that it could wait for the mbuf if not available immediately, this puts the requestor to sleep but does not count as a request being denied.

If the number of failed requests continues to increase, the system might have an mbuf leak. To help track down the problem, the `no` command parameter `net_malloc_police` can be set to 1, and the trace hook with ID 254 can be used with the `trace` command.

After an mbuf/cluster is allocated and pinned, it can be freed by the application. Instead of unpinning this buffer and giving it back to the system, it is left on a free-list based on the size of this buffer. The next time that a buffer is requested, it can be taken off this free-list to avoid the overhead of pinning. After the number of buffers on the free list reaches the highwater mark, buffers smaller than 4096 will be coalesced together into page-sized units so that they can be unpinned and given back to the system. When the buffers are given back to the system, the `freed` column is incremented. If the `freed` value consistently increases, the highwater mark is too low. In AIX 4.3.2 and later, the highwater mark is scaled according to the amount of RAM on the system.

netstat -v: The `netstat -v` command displays the statistics for each Common Data Link Interface (CDLI)-based device driver that is in operation. Interface-specific reports can be requested using the `tokstat`, `entstat`, `fddistat`, or `atmstat` commands.

Every interface has its own specific information and some general information. The following example shows the Token-Ring and Ethernet part of the `netstat -v` command; other interface parts are similar. With a different adapter, the statistics will differ somewhat. The most important output fields are highlighted.

```
# netstat -v

```

The highlighted fields are described as follows:

- **Transmit and Receive Errors**

Number of output/input errors encountered on this device. This field counts unsuccessful transmissions due to hardware/network errors.

These unsuccessful transmissions could also slow down the performance of the system.

- **Max Packets on S/W Transmit Queue**

Maximum number of outgoing packets ever queued to the software transmit queue.

An indication of an inadequate queue size is if the maximal transmits queued equals the current queue size (**xmt_que_size**). This indicates that the queue was full at some point.

To check the current size of the queue, use the **lsattr -El adapter** command (where adapter is, for example, tok0 or ent0). Because the queue is associated with the device driver and adapter for the interface, use the adapter name, not the interface name. Use the SMIT or the **chdev** command to change the queue size.

- **S/W Transmit Queue Overflow**

Number of outgoing packets that have overflowed the software transmit queue. A value other than zero requires the same actions as would be needed if the Max Packets on S/W Transmit Queue reaches the **xmt_que_size**. The transmit queue size must be increased.

- **Broadcast Packets**

Number of broadcast packets received without any error.

If the value for broadcast packets is high, compare it with the total received packets. The received broadcast packets should be less than 20 percent of the total received packets. If it is high, this could

be an indication of a high network load; use multicasting. The use of IP multicasting enables a message to be transmitted to a group of hosts, instead of having to address and send the message to each group member individually.

- **DMA Overrun**

The DMA Overrun statistic is incremented when the adapter is using DMA to put a packet into system memory and the transfer is not completed. There are system buffers available for the packet to be placed into, but the DMA operation failed to complete. This occurs when the MCA bus is too busy for the adapter to be able to use DMA for the packets. The location of the adapter on the bus is crucial in a heavily loaded system. Typically an adapter in a lower slot number on the bus, by having the higher bus priority, is using so much of the bus that adapters in higher slot numbers are not being served. This is particularly true if the adapters in a lower slot number are ATM or SSA adapters.

- **Max Collision Errors**

Number of unsuccessful transmissions due to too many collisions. The number of collisions encountered exceeded the number of retries on the adapter.

- **Late Collision Errors**

Number of unsuccessful transmissions due to the late collision error.

- **Timeout Errors**

Number of unsuccessful transmissions due to adapter reported timeout errors.

- **Single Collision Count**

Number of outgoing packets with single (only one) collision encountered during transmission.

- **Multiple Collision Count**

Number of outgoing packets with multiple (2 - 15) collisions encountered during transmission.

- **Receive Collision Errors**

Number of incoming packets with collision errors during reception.

- **No mbuf Errors**

Number of times that mbufs were not available to the device driver. This usually occurs during receive operations when the driver must obtain memory buffers to process inbound packets. If the mbuf pool for the requested size is empty, the packet will be discarded. Use the **netstat -m** command to confirm this, and increase the parameter **thewall**.

The No mbuf Errors value is interface-specific and not identical to the requests for mbufs denied from the **netstat -m** output. Compare the values of the example for the commands **netstat -m** and **netstat -v** (Ethernet and Token-Ring part).

To determine network performance problems, check for any Error counts in the **netstat -v** output.

Additional guidelines:

- To check for an overloaded Ethernet network, calculate (from the **netstat -v** command):

$(\text{Max Collision Errors} + \text{Timeouts Errors}) / \text{Transmit Packets}$

If the result is greater than 5 percent, reorganize the network to balance the load.

- Another indication for a high network load is (from the command **netstat -v**):

If the total number of collisions from the **netstat -v** output (for Ethernet) is greater than 10 percent of the total transmitted packets, as follows:

$\text{Number of collisions} / \text{Number of Transmit Packets} > 0.1$

netstat -p protocol: Shows statistics about the value specified for the protocol variable (udp, tcp, ip, icmp), which is either a well-known name for a protocol or an alias for it. Some protocol names and aliases are listed in the **/etc/protocols** file. A null response indicates that there are no numbers to report. If there is no statistics routine for it, the program report of the value specified for the protocol variable is unknown.

The following example shows the output for the ip protocol:

```

# netstat -p ip
ip:
:
    491351 total packets received
    0 bad header checksums
    0 with size smaller than minimum
    0 with data size < data length
    0 with header length < data size
    0 with data length < header length
    0 with bad options
    0 with incorrect version number
    25930 fragments received
    0 fragments dropped (dup or out of space)
    0 fragments dropped after timeout
    12965 packets reassembled ok
    475054 packets for this host
    0 packets for unknown/unsupported protocol
    0 packets forwarded
    3332 packets not forwardable
    0 redirects sent
    405650 packets sent from this host
    0 packets sent with fabricated ip header
    0 output packets dropped due to no bufs, etc.
    0 output packets discarded due to no route
    5498 output datagrams fragmented
    10996 fragments created
    0 datagrams that can't be fragmented
    0 IP Multicast packets dropped due to no receiver
    0 ipintrq overflows

```

The highlighted fields are described as follows:

- **Total Packets Received**
Number of total IP datagrams received.
- **Bad Header Checksum or Fragments Dropped**
If the output shows bad header checksum or fragments dropped due to dup or out of space, this indicates either a network that is corrupting packets or device driver receive queues that are not large enough.
- **Fragments Received**
Number of total fragments received.
- **Dropped after Timeout**
If the fragments dropped after timeout is other than zero, then the time to life counter of the ip fragments expired due to a busy network before all fragments of the datagram arrived. To avoid this, use the **no** command to increase the value of the **ipfragttl** network parameter. Another reason could be a lack of mbufs; increase **thewall**.
- **Packets Sent from this Host**
Number of IP datagrams that were created and sent out from this system. This counter does not include the forwarded datagrams (passthrough traffic).
- **Fragments Created**
Number of fragments created in this system when IP datagrams were sent out.

When viewing IP statistics, look at the ratio of packets received to fragments received. As a guideline for small MTU networks, if 10 percent or more of the packets are getting fragmented, you should investigate further to determine the cause. A large number of fragments indicates that protocols above the IP layer on remote hosts are passing data to IP with data sizes larger than the MTU for the interface. Gateways/routers in the network path might also have a much smaller MTU size than the other nodes in the network. The same logic can be applied to packets sent and fragments created.

Fragmentation results in additional CPU overhead so it is important to determine its cause. Be aware that some applications, by their very nature, can cause fragmentation to occur. For example, an application that sends small amounts of data can cause fragments to occur. However, if you know the application is sending large amounts of data and fragmentation is still occurring, determine the cause. It is likely that the MTU size used is not the MTU size configured on the systems.

The following example shows the output for the udp protocol:

```
# netstat -p udp
udp:
    11521194 datagrams received
    0 incomplete headers
    0 bad data length fields
    0 bad checksums
    16532 dropped due to no socket
    232850 broadcast/multicast datagrams dropped due to no socket
    77 socket buffer overflows
    11271735 delivered
    796547 datagrams output
```

Statistics of interest are:

- **Bad Checksums**

Bad checksums could happen due to hardware card or cable failure.

- **Dropped Due to No Socket**

Number of received UDP datagrams of that destination socket ports were not opened. As a result, the ICMP Destination Unreachable - Port Unreachable message must have been sent out. But if the received UDP datagrams were broadcast datagrams, ICMP errors are not generated. If this value is high, investigate how the application is handling sockets.

- **Socket Buffer Overflows**

Socket buffer overflows could be due to insufficient transmit and receive UDP sockets, too few **nfsd** daemons, or too small **nfs_socketsize**, **udp_recvspace** and **sb_max** values.

If the **netstat -p udp** command indicates socket overflows, then you might need to increase the number of the **nfsd** daemons on the server. First, check the affected system for CPU or I/O saturation, and verify the recommended setting for the other communication layers by using the **no -a** command. If the system is saturated, you must either to reduce its load or increase its resources.

The following example shows the output for the tcp protocol:

```
# netstat -p tcp
tcp:
    63726 packets sent
        34309 data packets (6482122 bytes)
        198 data packets (161034 bytes) retransmitted
        17437 ack-only packets (7882 delayed)
        0 URG only packets
        0 window probe packets
        3562 window update packets
        8220 control packets
    71033 packets received
        35989 acks (for 6444054 bytes)

    26 keepalive probes sent
    1 connection dropped by keepalive
0 connections in timewait reused
0 delayed ACKs for SYN
0 delayed ACKs for FIN
0 send_and_disconnects

```

Statistics of interest are:

- Packets Sent
- Data Packets
- Data Packets Retransmitted
- Packets Received
- Completely Duplicate Packets
- Retransmit Timeouts

For the TCP statistics, compare the number of packets sent to the number of data packets retransmitted. If the number of packets retransmitted is over 10-15 percent of the total packets sent, TCP is experiencing timeouts indicating that network traffic may be too high for acknowledgments (ACKs) to return before a timeout. A bottleneck on the receiving node or general network problems can also cause TCP retransmissions, which will increase network traffic, further adding to any network performance problems.

Also, compare the number of packets received with the number of completely duplicate packets. If TCP on a sending node times out before an ACK is received from the receiving node, it will retransmit the packet. Duplicate packets occur when the receiving node eventually receives all the retransmitted packets. If the number of duplicate packets exceeds 10-15 percent, the problem may again be too much network traffic or a bottleneck at the receiving node. Duplicate packets increase network traffic.

The value for retransmit timeouts occurs when TCP sends a packet but does not receive an ACK in time. It then resends the packet. This value is incremented for any subsequent retransmittals. These continuous retransmittals drive CPU utilization higher, and if the receiving node does not receive the packet, it eventually will be dropped.

netstat -s: The **netstat -s** command shows statistics for each protocol (while the **netstat -p** command shows the statistics for the specified protocol).

netstat -s -s: The undocumented **-s -s** option shows only those lines of the **netstat -s** output that are not zero, making it easier to look for error counts.

netstat -s -Z: This is an undocumented function of the **netstat** command. It clears all the statistic counters for the **netstat -s** command to zero.

netstat -r: Another option relevant to performance is the display of the discovered Path Maximum Transmission Unit (PMTU).

For two hosts communicating across a path of multiple networks, a transmitted packet will become fragmented if its size is greater than the smallest MTU of any network in the path. Because packet fragmentation can result in reduced network performance, it is desirable to avoid fragmentation by transmitting packets with a size no larger than the smallest MTU in the network path. This size is called the *path MTU*.

Use the **netstat -r** command to display this value. In the following is example the **netstat -r -f inet** command is used to display only the routing tables:

```
# netstat -r -f inet
Routing tables
Destination      Gateway          Flags  Refs    Use  PMTU If  Exp  Groups

(Note: N/A -> Not Applicable)

The Devices layer shows number of packets coming into the adapter, going out of the adapter, and number of packets dropped on input and output. There are various causes of adapter errors, and the **netstat -v** command can be examined for more details.

The Drivers layer shows packet counts handled by the device driver for each adapter. Output of the **netstat -v** command is useful here to determine which errors are counted.

The Demuxer values show packet counts at the demux layer, and Idrops here usually indicate that filtering has caused packets to be rejected (for example, Netware or DecNet packets being rejected because these are not handled by the system under examination).

Details for the Protocols layer can be seen in the output of the **netstat -s** command.

Note: In the statistics output, a N/A displayed in a field value indicates the count is not applicable. For the NFS/RPC statistics, the number of incoming packets that pass through RPC are the same packets which pass through NFS, so these numbers are not summed in the NFS/RPC Total field, hence the N/A. NFS has no outgoing packet or outgoing packet drop counters specific to NFS and RPC. Therefore, individual counts have a field value of N/A, and the cumulative count is stored in the NFS/RPC Total field.

The netpmon Command

The **netpmon** command uses the trace facility to obtain a detailed picture of network activity during a time interval. Because it uses the trace facility, the **netpmon** command can be run only by a root user or by a member of the system group.

Also, the **netpmon** command cannot run together with any of the other trace-based performance commands such as **tprof** and **filemon**. In its usual mode, the **netpmon** command runs in the background while one or more application programs or system commands are being executed and monitored.

The **netpmon** command focuses on the following system activities:

- CPU usage
 - By processes and interrupt handlers
 - How much is network-related
 - What causes idle time
- Network device driver I/O
 - Monitors I/O operations through all Ethernet, Token-Ring, and Fiber-Distributed Data Interface (FDDI) network device drivers.
 - In the case of transmission I/O, the command monitors utilizations, queue lengths, and destination hosts. For receive I/O, the command also monitors time in the demux layer.
- Internet socket calls
 - Monitors **send()**, **recv()**, **sendto()**, **recvfrom()**, **sendmsg()**, **read()**, and **write()** subroutines on Internet sockets.
 - Reports statistics on a per-process basis for the Internet Control Message Protocol (ICMP), Transmission Control Protocol (TCP), and the User Datagram Protocol (UDP).
- NFS I/O
 - On client: RPC requests, NFS read/write requests.
 - On server: Per-client, per-file, read/write requests.

The following will be computed:

- Response times and sizes associated with transmit and receive operations at the device driver level.
- Response times and sizes associated with all types of Internet socket read and write system calls.

- Response times and sizes associated with NFS read and write system calls.
- Response times associated with NFS remote procedure call requests.

To determine whether the **netpmon** command is installed and available, run the following command:

```
# ls1pp -lI perfagent.tools
```

Tracing is started by the **netpmon** command, optionally suspended with the **trcoff** subcommand and resumed with the **trcon** subcommand, and terminated with the **trcstop** subcommand. As soon as tracing is terminated, the **netpmon** command writes its report to standard output.

Using netpmon

The **netpmon** command will start tracing immediately unless the **-d** option is used. Use the **trcstop** command to stop tracing. At that time, all the specified reports are generated, and the **netpmon** command exits. In the client-server environment, use the **netpmon** command to view how networking affects the overall performance. It can be run on both client and server.

The **netpmon** command can read the I/O trace data from a specified file, instead of from the real-time trace process. In this case, the **netpmon** report summarizes the network activity for the system and period represented by the trace file. This offline processing method is useful when it is necessary to postprocess a trace file from a remote machine or perform the trace data collection at one time and postprocess it at another time.

The **trcrpt -r** command must be executed on the trace logfile and redirected to another file, as follows:

```
# gennames > gennames.out
# trcrpt -r trace.out > trace.rpt
```

At this point, an adjusted trace logfile is fed into the **netpmon** command to report on I/O activity captured by a previously recorded trace session as follows:

```
# netpmon -i trace.rpt -n gennames.out | pg
```

In this example, the **netpmon** command reads file system trace events from the **trace.rpt** input file. Because the trace data is already captured on a file, the **netpmon** command does not put itself in the background to allow application programs to be run. After the entire file is read, a network activity report will be displayed on standard output (which, in this example, is piped to the **pg** command).

If the **trace** command was run with the **-C all** flag, then run the **trcrpt** command also with the **-C all** flag (see Formatting a Report from trace -C Output).

The following **netpmon** command running on an NFS server executes the **sleep** command and creates a report after 400 seconds. During the measured interval, a copy to an NFS-mounted file system **/nfs_mnt** is taking place.

```
# netpmon -o netpmon.out -0 all; sleep 400; trcstop
```

With the **-O** option, you can specify the report type to be generated. Valid report type values are:

```
cpu    CPU usage
dd     Network device-driver I/O
so     Internet socket call I/O
nfs    NFS I/O
all    All reports are produced. This is the default value
# cat netpmon.out
```

```
Thu Jan 21 15:02:45 2000
System: AIX itsosmp Node: 4 Machine: 00045067A000
```

401.053 secs in measured interval

The output of the **netpmon** command is composed of two different types of reports: *global* and *detailed*. The global reports list statistics as follows:

- Most active processes
- First-level interrupt handlers
- Second-level interrupt handlers
- Network device drivers
- Network device-driver transmits
- TCP socket calls
- NFS server or client statistics

The global reports are shown at the beginning of the **netpmon** output and are the occurrences during the measured interval. The detailed reports provide additional information for the global reports. By default, the reports are limited to the 20 most active statistics measured. All information in the reports is listed from top to bottom as most active to least active.

Global Reports of netpmon

The reports generated by the **netpmon** command begin with a header, which identifies the date, the machine ID, and the length of the monitoring period in seconds. The header is followed by a set of global and detailed reports for all specified report types.

Process CPU Usage Statistics: Each row describes the CPU usage associated with a process. Unless the verbose (-v) option is specified, only the 20 most active processes are included in the list. At the bottom of the report, CPU usage for all processes is totaled, and CPU idle time is reported. The idle time percentage number is calculated from the idle time divided by the measured interval. The difference between the CPU time totals and measured interval is due to Interrupt handlers.

The Network CPU % is the percentage of total time that this process spent executing network-related code.

If the -t flag is used, a thread CPU usage statistic is also present. Each process row described above is immediately followed by rows describing the CPU usage of each thread owned by that process. The fields in these rows are identical to those for the process, except for the name field. Threads are not named.

In the example report, the Idle time percentage number (76.114 percent) shown in the global CPU usage report is calculated from the Idle time (1221.0235) divided by the measured interval times 4 (401.053 times 4), because there are four CPUs in this server. If you want to look at each CPU's activity, you can use **sar**, **ps**, or any other SMP-specific command. Similar calculation applies to the total CPU % that is occupied by all processes. The Idle time is due to network I/O. The difference between the CPU Time totals (1221.0235 + 358.315) and the measured interval is due to interrupt handlers and the multiple CPUs. It appears that in the example report, the majority of the CPU usage was network-related: $(20.787 / 22.336) = 93.07$ percent. About 77.664 percent of CPU usage is either CPU idle or CPU wait time.

Note: If the result of total network CPU % divided by total CPU % is greater than 0.5 from Process CPU Usage Statistics for NFS server, then the majority of CPU usage is network-related.

This method is also a good way to view CPU usage by process without tying the output to a specific program.

First Level Interrupt Handler CPU Usage Statistics: Each row describes the CPU usage associated with a first-level interrupt handler (FLIH). At the bottom of the report, CPU usage for all FLIHs is totaled.

CPU Time

Total amount of CPU time used by this FLIH

CPU %

CPU usage for this interrupt handler as a percentage of total time

Network CPU %

Percentage of total time that this interrupt handler executed on behalf of network-related events

Second Level Interrupt Handler CPU Usage Statistics: Each row describes the CPU usage associated with a second-level interrupt handler (SLIH). At the bottom of the report, CPU usage for all SLIHs is totaled.

Network Device-Driver Statistics (by Device): Each row describes the statistics associated with a network device.

Device

Name of special file associated with device

Xmit Pkts/s

Packets per second transmitted through this device

Xmit Bytes/s

Bytes per second transmitted through this device

Xmit Util

Busy time for this device, as a percent of total time

Xmit QLen

Number of requests waiting to be transmitted through this device, averaged over time, including any transaction currently being transmitted

Recv Pkts/s

Packets per second received through this device

Recv Bytes/s

Bytes per second received through this device

Recv Demux

Time spent in demux layer as a fraction of total time

In this example, the Xmit QLen is only 0.046. This number is very small compared to its default size (30). Its Recv Bytes/s is 273994, much smaller than the Token-Ring transmit speed (16 Mb/s). Therefore, in this case, the network is not saturated, at least from this system's view.

Network Device-Driver Transmit Statistics (by Destination Host): Each row describes the amount of transmit traffic associated with a particular destination host, at the device-driver level.

Host Destination host name. An asterisk (*) is used for transmissions for which no host name can be determined.

Pkts/s Packets per second transmitted to this host.

Bytes/s

Bytes per second transmitted to this host.

TCP Socket Call Statistics for Each Internet Protocol (by Process): These statistics are shown for each used Internet protocol. Each row describes the amount of **read()** and **write()** subroutine activity on sockets of this protocol type associated with a particular process. At the bottom of the report, all socket calls for this protocol are totaled.

NFS Server Statistics (by Client): Each row describes the amount of NFS activity handled by this server on behalf of a particular client. At the bottom of the report, calls for all clients are totaled.

On a client machine, the NFS server statistics are replaced by the NFS client statistics (NFS Client Statistics for each Server (by File), NFS Client RPC Statistics (by Server), NFS Client Statistics (by Process)).

Detailed Reports of netpmon

Detailed reports are generated for all requested (-O) report types. For these report types, a detailed report is produced in addition to the global reports. The detailed reports contain an entry for each entry in the global reports with statistics for each type of transaction associated with the entry.

Transaction statistics consist of a count of the number of transactions for that type, followed by response time and size distribution data (where applicable). The distribution data consists of average, minimum, and maximum values, as well as standard deviations. Roughly two-thirds of the values are between average minus standard deviation and average plus standard deviation. Sizes are reported in bytes. Response times are reported in milliseconds.

Detailed Second-Level Interrupt Handler CPU-Usage Statistics: The output fields are described as follows:

SLIH Name of second-level interrupt handler

count Number of interrupts of this type

cpu time (msec)

CPU usage statistics for handling interrupts of this type

Detailed Network Device-Driver Statistics (by Device): The output fields are described as follows:

DEVICE

Path name of special file associated with device

recv packets

Number of packets received through this device

recv sizes (bytes)

Size statistics for received packets

recv times (msec)

Response time statistics for processing received packets

demux times (msec)

Time statistics for processing received packets in the demux layer

xmit packets

Number of packets transmitted through this device

xmit sizes (bytes)

Size statistics for transmitted packets

xmit times (msec)

Response time statistics for processing transmitted packets

There are other detailed reports, such as Detailed Network Device-Driver Transmit Statistics (by Host) and Detailed TCP Socket Call Statistics for Each Internet Protocol (by Process). For an NFS client, there are the Detailed NFS Client Statistics for Each Server (by File), Detailed NFS Client RPC Statistics (by Server), and Detailed NFS Client Statistics (by Process) reports. For an NFS server, there is the Detailed NFS Server Statistics (by Client) report. They have similar output fields as explained above.

In the example, the results from the Detailed Network Device-Driver Statistics lead to the following:

- $\text{recv bytes} = 80584 \text{ packets} * 1364 \text{ bytes/packet} = 109,916,576 \text{ bytes}$
- $\text{xmit bytes} = 12678 \text{ packets} * 152 \text{ bytes/packet} = 1,927,056 \text{ bytes}$
- $\text{total bytes exchanged} = 109,916,576 + 1,927,056 = 111,843,632 \text{ bytes}$
- $\text{total bits exchanged} = 111,843,632 * 8 \text{ bits/byte} = 894,749,056 \text{ bits}$
- $\text{transmit speed} = 894,749,056 / 401.053 = 2.23 \text{ Mb/s}$ (assuming that the copy took the entire monitoring period)

As in the global device driver report, you can conclude that this case is not network-saturated. The average receive size is 1363.6 bytes, near to the default MTU (maximum transmission unit) value, which is 1492 when the device is a Token-Ring card. If this value is larger than the MTU (from **lsattr -E -l interface**, replacing *interface* with the interface name, such as en0 or tr0, you could change the MTU or adapter transmit-queue length value to get better performance with the following command:

```
# ifconfig tr0 mtu 8500
```

OR

```
# chdev -l 'tok0' -a xmt_que_size='150'
```

If the network is congested already, changing the MTU or queue value will not help.

Note:

- If transmit and receive packet sizes are small on the device driver statistics report, then increasing the current MTU size will probably result in better network performance.
- If system wait time due to network calls is high from the network wait time statistics for the NFS client report, the poor performance is due to the network.

Limitations of netpmn

The **netpmn** command uses the trace facility to collect the statistics. Therefore, it has an impact on the system workload, as follows.

- In a moderate, network-oriented workload, the **netpmn** command increases overall CPU utilization by 3-5 percent.
- In a CPU-saturated environment with little I/O of any kind, the **netpmn** command slowed a large compile by about 3.5 percent.

To alleviate these situations, use offline processing and on systems with many CPUs use the **-C all** flag with the **trace** command.

The traceroute Command

While the **ping** command confirms IP network reachability, you cannot pinpoint and improve some isolated problems. Consider the following situation:

- When there are many hops (for example, gateways or routes) between your system and the destination, and there seems to be a problem somewhere along the path. The destination system may have a problem, but you need to know where a packet is actually lost.
- The **ping** command hangs up and does not tell you the reasons for a lost packet.

The **traceroute** command can inform you where the packet is located and why the route is lost. If your packets must pass through routers and links, which belong to and are managed by other organizations or companies, it is difficult to check the related routers through the **telnet** command. The **traceroute** command provides a supplemental role to the **ping** command.

Note: The **traceroute** command is intended for use in network testing, measurement, and management. It should be used primarily for manual fault isolation. Because of the load it imposes on the network, do not use the **traceroute** command during typical operations or from automated scripts.

Successful traceroute Examples

The **traceroute** command uses UDP packets and uses the ICMP error-reporting function. It sends a UDP packet three times to each gateway or router on the way. It starts with the nearest gateway and expands the search by one hop. Finally, the search gets to the destination system. In the output, you see the gateway name, the gateway's IP address, and three round-trip times for the gateway. See the following example:

```
# traceroute wave
trying to get source for wave
source should be 9.53.155.187
traceroute to wave.austin.ibm.com (9.53.153.120) from 9.53.155.187 (9.53.155.187), 30 hops max
outgoing MTU = 1500
 1 9.111.154.1 (9.111.154.1) 5 ms 3 ms 2 ms
 2 wave (9.53.153.120) 5 ms 5 ms 5 ms
```

Following is another example:

```
# traceroute wave
trying to get source for wave
source should be 9.53.155.187
traceroute to wave.austin.ibm.com (9.53.153.120) from 9.53.155.187 (9.53.155.187), 30 hops max
outgoing MTU = 1500
 1 9.111.154.1 (9.111.154.1) 10 ms 2 ms 3 ms
 2 wave (9.53.153.120) 8 ms 7 ms 5 ms
```

After the address resolution protocol (ARP) entry expired, the same command was repeated. Note that the first packet to each gateway or destination took a longer round-trip time. This is due to the overhead caused by the ARP. If a public-switched network (WAN) is involved in the route, the first packet consumes

a lot of memory due to a connection establishment and may cause a timeout. The default timeout for each packet is 3 seconds. You can change it with the **-w** option.

The first 10 ms is due to the ARP between the source system (9.53.155.187) and the gateway 9.111.154.1. The second 8 ms is due to the ARP between the gateway and the final destination (wave). In this case, you are using DNS, and every time before the **traceroute** command sends a packet, the DNS server is searched.

Failed traceroute Examples

For a long path to your destination or complex network routes, you may see a lot of problems with the **traceroute** command. Because many things are implementation-dependent, searching for the problem may only waste your time. If all routers or systems involved are under your control, you may be able to investigate the problem completely.

Gateway (Router) Problem: In the following example, packets were sent from the system 9.53.155.187. There are two router systems on the way to the bridge. The routing capability was intentionally removed from the second router system by setting the option **ipforwarding** of the **no** command to 0. See the following example:

```
# traceroute lamar
trying to get source for lamar
source should be 9.53.155.187
traceroute to lamar.austin.ibm.com (9.3.200.141) from 9.53.155.187 (9.53.155.187), 30 hops max
outgoing MTU = 1500
 1 9.111.154.1 (9.111.154.1) 12 ms 3 ms 2 ms
 2 9.111.154.1 (9.111.154.1) 3 ms !H * 6 ms !H
```

If an ICMP error message, excluding Time Exceeded and Port Unreachable, is received, it is displayed as follows:

```
!H    Host Unreachable
!N    Network Unreachable
!P    Protocol Unreachable
!S    Source route failed
!F    Fragmentation needed
```

Destination System Problem: When the destination system does not respond within a 3-second time-out interval, all queries are timed out, and the results are displayed with an asterisk (*).

```
# traceroute chuis
trying to get source for chuis
source should be 9.53.155.187
traceroute to chuis.austin.ibm.com (9.53.155.188) from 9.53.155.187 (9.53.155.187), 30 hops max
outgoing MTU = 1500
 1 * * *
 2 * * *
 3 * * *
^C#
```

If you think that the problem is due to a communication link, use a longer timeout period with the **-w** flag. Although rare, all the ports queried might have been used. You can change the ports and try again.

Number of "hops" to Destination: Another output example might be as follows:

```
# traceroute mysystem.university.edu (129.2.130.22)
traceroute to mysystem.university.edu (129.2.130.22), 30 hops max
 1 helios.ee.lbl.gov (129.3.112.1) 0 ms 0 ms 0 ms
 2 lilac-dmc.university.edu (129.2.216.1) 39 ms 19 ms 39 ms
 3 lilac-dmc.university.edu (129.2.215.1) 19 ms 39 ms 19 ms
 4 ccngw-ner-cc.university.edu (129.2.135.23) 39 ms 40 ms 19 ms
 5 ccn-nerif35.university.edu (129.2.167.35) 39 ms 39 ms 39 ms
```

```

6 csgw/university.edu (129.2.132.254) 39 ms 59 ms 39 ms
7 * * *
8 * * *
9 * * *
10 * * *
11 * * *
12 * * *
13 rip.university.EDU (129.2.130.22) 59 ms! 39 ms! 39 ms!

```

In this example, exactly half of the 12 gateway hops (13 is the final destination) are "missing." However, these hops were actually not gateways. The destination host used the time to live (ttl) from the arriving datagram as the ttl in its ICMP reply; thus, the reply timed out on the return path. Because ICMPs are not sent for ICMPs, no notice was received. The ! (exclamation mark) after each round-trip time indicates some type of software incompatibility problem. (The cause was diagnosed after the **traceroute** command issued a probe of twice the path length. The destination host was really only seven hops away.)

The iptrace daemon, and the ipreport and ipfilter Commands

You can use many tools for observing network activity. Some run under the operating system, others run on dedicated hardware. One tool that can be used to obtain a detailed, packet-by-packet description of the LAN activity generated by a workload is the combination of the **iptrace** daemon and the **ipreport** command. To use the **iptrace** daemon with operating system version 4, you need the **bos.net.tcp.server** fileset. The **iptrace** daemon is included in this fileset, as well as some other useful commands such as the **trpt** and **tcdump** commands. The **iptrace** daemon can only be started by a root user.

By default, the **iptrace** daemon traces all packets. The option **-a** allows exclusion of address resolution protocol (ARP) packets. Other options can narrow the scope of tracing to a particular source host (**-s**), destination host (**-d**), or protocol (**-p**). Because the **iptrace** daemon can consume significant amounts of processor time, be as specific as possible when you describe the packets you want traced.

Because **iptrace** is a daemon, start the **iptrace** daemon with the **startsrc** command rather than directly from the command line. This method makes it easier to control and shut down cleanly. A typical example would be as follows:

```
# startsrc -s iptrace -a "-i tr0 /home/user/iptrace/log1"
```

This command starts the **iptrace** daemon with instructions to trace all activity on the Token-Ring interface, tr0, and place the trace data in **/home/user/iptrace/log1**. To stop the daemon, use the following:

```
# stopsrc -s iptrace
```

If you did not start the **iptrace** daemon with the **startsrc** command, you must use the **ps** command to find its process ID with and terminate it with the **kill** command.

The **ipreport** command is a formatter for the log file. Its output is written to standard output. Options allow recognition and formatting of RPC packets (**-r**), identifying each packet with a number (**-n**), and prefixing each line with a 3-character string that identifies the protocol (**-s**). A typical **ipreport** command to format the **log1** file just created (which is owned by the root user) would be as follows:

```
# ipreport -ns log1 >log1_formatted
```

This would result in a sequence of packet reports similar to the following examples. The first packet is the first half of a **ping** packet. The fields of most interest are as follows:

- The source (SRC) and destination (DST) host address, both in dotted decimal and in ASCII
- The IP packet length (ip_len)
- The indication of the higher-level protocol in use (ip_p)

```

Packet Number 131

```

The **ipfilter** command extracts different operation headers from an **ipreport** output file and displays them in a table. Some customized NFS information regarding requests and replies is also provided.

To determine whether the **ipfilter** command is installed and available, run the following command:

```
# ls1pp -lI perfagent.tools
```

An example command is as follows:

```
# ipfilter log1_formatted
```

The operation headers currently recognized are: udp, nfs, tcp, ipx, icmp. The **ipfilter** command has three different types of reports, as follows:

- A single file (**ipfilter.all**) that displays a list of all the selected operations. The table displays packet number, Time, Source & Destination, Length, Sequence #, Ack #, Source Port, Destination Port, Network Interface, and Operation Type.
- Individual files for each selected header (**ipfilter.udp**, **ipfilter.nfs**, **ipfilter.tcp**, **ipfilter.ipx**, **ipfilter.icmp**). The information contained is the same as **ipfilter.all**.
- A file **nfs.rpt** that reports on NFS requests and replies. The table contains: Transaction ID #, Type of Request, Status of Request, Call Packet Number, Time of Call, Size of Call, Reply Packet Number, Time of Reply, Size of Reply, and Elapsed millisecond between call and reply.

Adapter Statistics

The commands in this section provide output comparable to the **netstat -v** command. They allow you to reset adapter statistics (**-r**) and to get more detailed output (**-d**) than the **netstat -v** command output provides.

The entstat Command

The **entstat** command displays the statistics gathered by the specified Ethernet device driver. The user can optionally specify that the device-specific statistics be displayed in addition to the device-generic statistics. Using the **-d** option will list any extended statistics for this adapter and should be used to ensure all statistics are displayed. If no flags are specified, only the device-generic statistics are displayed.

The **entstat** command is also invoked when the **netstat** command is run with the **-v** flag. The **netstat** command does not issue any **entstat** command flags.

```
# entstat ent0
-----
ETHERNET STATISTICS (ent0) :
Device Type: IBM 10/100 Mbps Ethernet PCI Adapter (23100020)

              Simplex 64BitSupport
```

In the above report, you may want to concentrate on:

Transmit Errors

Number of output errors encountered on this device. This is a counter for unsuccessful transmissions due to hardware/network errors.

Receive Errors

Number of input errors encountered on this device. This is a counter for unsuccessful reception due to hardware/network errors.

Packets Dropped

Number of packets accepted by the device driver for transmission which were not (for any reason) given to the device.

Max Packets on S/W Transmit Queue

Maximum number of outgoing packets ever queued to the software transmit queue.

S/W Transmit Queue Overflow

Number of outgoing packets that have overflowed the transmit queue.

No Resource Errors

Number of incoming packets dropped by the hardware due to lack of resources. This error usually occurs because the receive buffers on the adapter were exhausted. Some adapters may have the size of the receive buffers as a configurable parameter. Check the device configuration attributes (or SMIT helps) for possible tuning information.

Single Collision Count/Multiple Collision Count

Number of collisions on an Ethernet network. These collisions are accounted for here rather than in the collision column of the output of the **netstat -i** command.

Notice in this example, the Ethernet adapter is behaving well because there are no Receive Errors. These errors are sometimes caused when a saturated network only transmits partial packets. The partial packets are eventually retransmitted successfully but are recorded as receive errors.

If you receive S/W Transmit Queue Overflow errors, the value of Max Packets on S/W Transmit Queue will correspond to the transmit queue limit for this adapter (**xmt_que_size**).

Note: These values can represent the *hardware queue* if the adapter does not support a software transmit queue. If there are transmit-queue overflows, then increased the hardware or software queue limits for the driver.

If there are not enough receive resources, this would be indicated by Packets Dropped: and depending on the adapter type, would be indicated by Out of Rcv Buffers or No Resource Errors: or some similar counter.

The elapsed time displays the real-time period that has elapsed since the last time the statistics were reset. To reset the statistics, use the **entstat -r adapter_name** command.

Similar output can be displayed for Token-Ring, FDDI, and ATM interfaces using the **tokstat**, **fddistat**, and **atmstat** commands.

The tokstat Command

The **tokstat** command displays the statistics gathered by the specified Token-Ring device driver. The user can optionally specify that the device-specific statistics be displayed in addition to the device driver statistics. If no flags are specified, only the device driver statistics are displayed.

This command is also invoked when the **netstat** command is run with the **-v** flag. The **netstat** command does not issue any **tokstat** command flags.

The output produced by the **tokstat tok0** command and the problem determination are similar to that described in The entstat Command.

The fddistat Command

The **fddistat** command displays the statistics gathered by the specified FDDI device driver. The user can optionally specify that the device-specific statistics be displayed in addition to the device driver statistics. If no flags are specified, only the device driver statistics are displayed.

This command is also invoked when the **netstat** command is run with the **-v** flag. The **netstat** command does not issue any **fdistat** command flags.

The output produced by the **fdistat fddi0** command and the problem determination are similar to that described in The **entstat** Command.

The **atmstat** Command

The **atmstat** command displays the statistics gathered by the specified ATM device driver. The user can optionally specify that the device-specific statistics be displayed in addition to the device driver statistics. If no flags are specified, only the device driver statistics are displayed.

The output produced by the **atmstat atm0** command and the problem determination are similar to that described in The **entstat** Command.

The **no** Command

Use the **no** command to display current network values and to change options.

- a** Prints all options and current values (example: **no -a**)
- d** Sets options back to default (example: **no -d thewall**)
- o** *option=NewValue* (example: **no -o thewall=16384**)

For a listing of all attributes for the **no** command, see Network Option Tunable Parameters.

Some network attributes are run-time attributes that can be changed at any time. Others are load-time attributes that must be set before the **netinet** kernel extension is loaded.

Note: When the **no** command is used to change parameters, the change is in effect only until the next system boot. At that point, all parameters are initially reset to their defaults. To make the change permanent, put the appropriate **no** command in the **/etc/rc.net** file.

If your system uses Berkeley-style network configuration, set the attributes near the top of the **/etc/rc.bsdnet** file. If you use an SP system, edit the **tuning.cust** file as documented in the *RS/6000 SP: Installation and Relocation* manual.

Note: The **no** command performs no-range checking. If it is used incorrectly, the **no** command can cause your system to become inoperable.

The following tuning sections discuss some of the **no** command attributes and how to adjust them.

Tuning TCP and UDP Performance

The optimal settings of the tunable communications parameters vary with the type of LAN, as well as with the communications-I/O characteristics of the predominant system and application programs. The following sections describe the global principles of communications tuning, followed by specific recommendations for the different types of LAN.

Overall Recommendations

You can choose to tune primarily either for maximum throughput or for minimum memory use. Some recommendations apply to one or the other; some apply to both. Recommended application block sizes for different adapter devices are as follows:

Device Name	Application Block Size
Ethernet	Multiples of 4096
Token-Ring (4 Mb)	Multiples of 4096

Token-Ring (16 Mb)	Multiples of 4096
FDDI (tcp)	Multiples of 4096
SOCC (tcp)	28672 bytes
HIPPI	65536 bytes
ATM	Multiples of 4096

Maximizing Throughput

Use the following recommendations to tune for maximum throughput:

Request-Response Protocols: Follow these guidelines:

- For maximum number of transactions per second, use the smallest feasible messages.
- For maximum bytes per second, use messages that are at least 1000 bytes and equal to or just less than a multiple of 4096 bytes.
- If the requests and responses are fixed-size and fit into one datagram, use UDP.
 - If possible, make the write sizes equal to the following:
(a multiple of the MTU size minus 28 bytes to allow for standard IP and UDP headers).
 - In general, it is more efficient for the application to write large messages and have them fragmented and reassembled by IP, than to have the application write multiple times.
 - Whenever possible, use the **connect()** subroutine to associate an address with the UDP socket. This may not be possible on a server that is communicating with a number of clients through a single socket.
- If the requests or responses are variable-size, use TCP with the TCP_NODELAY option. Measurements indicate that the overhead of TCP compared with UDP is negligible, especially if optimum write sizes are used.
 - To avoid data copies in the kernel, make write sizes greater than 512 bytes.
 - Make writes equal to or slightly less than, a multiple of MTU size. This will avoid the sending of a segment (packet) with just a few bytes in it.

Streaming: Follow these guidelines:

- TCP provides higher throughput than UDP and ensures reliable delivery.
- Writes should be in multiples of 16384 bytes. If possible, writes should be the size of the MSS (see Tuning TCP Maximum Segment Size).

Minimizing Memory

Use the following recommendations to tune for minimizing memory usage:

- If your traffic is predominantly local, use the largest MTU size that is supported by your LAN type. This minimizes the fragmentation of packets exchanged by local systems. The offsetting cost is fragmentation in gateways that connect your LAN to other LANs with smaller MTUs (see Tuning TCP Maximum Segment Size).
- Whenever possible, application programs should read and write in quantities of either:
 - Less than or equal to 512 bytes
 - OR
 - Slightly less than or equal to 4096 bytes (or multiples thereof)

If the applications were using TCP, both time and memory would be wasted. TCP tries to form outbound data into MTU-sized packets. If the MTU of the LAN were larger than 14976 bytes, TCP would put the sending thread to sleep when the **tcp_sendspace** limit was reached. To force the data to be written, a timeout ACK from the receiver would be required.

Adapter Transmit and Receive Queue Tuning

Most communication drivers provide a set of tunable parameters to control transmit and receive resources. These parameters typically control the transmit queue and receive queue limits, but may also control the number and size of buffers or other resources. These parameters limit the number of buffers or packets that may be queued for transmit or limit the number of receive buffers that are available for receiving packets. These parameters can be tuned to ensure enough queueing at the adapter level to handle the peak loads generated by the system or the network.

Following are some general guidelines:

- Tune transmit queues when the CPU is faster than the network (more common on multi-processor systems where many CPUs are transmitting to a single adapter).
- Tune transmit queues when socket buffer sizes are large.
- Tune receive queues when there is very bursty traffic.
- Tune transmit and receive queues when there is high rate of small-sized packets.

Transmit Queues

For transmit, the device drivers may provide a *transmit queue* limit. There may be both hardware queue and software queue limits, depending on the driver and adapter. Some drivers have only a hardware queue; some have both hardware and software queues. Some drivers internally control the hardware queue and only allow the software queue limits to be modified. Generally, the device driver will queue a transmit packet directly to the adapter hardware queue. If the system CPU is fast relative to the speed of the network, or on an SMP system, the system may produce transmit packets faster than they can be transmitted on the network. This will cause the hardware queue to fill. After the hardware queue is full, some drivers provide a software queue and they will then queue to the software queue. If the software transmit queue limit is reached, then the transmit packets are discarded. This can affect performance because the upper-level protocols must then time out and retransmit the packet.

Prior to AIX 4.2.1, the upper limits on the transmit queues were in the range of 150 to 250, depending on the specific adapter. The system default values were low, typically 30. With AIX 4.2.1 and later, the transmit queue limits were increased on most of the device drivers to 2048 buffers. The default values were also increased to 512 for most of these drivers. The default values were increased because the faster CPUs and SMP systems can overrun the smaller queue limits.

Following are examples of MCA adapter transmit queue sizes:

MCA Adapter Type	Default	Range
Ethernet	512	20 - 2048
10/100 Ethernet	64	16,32,64,128,256
Token-Ring	99 or 512	32 - 2048
FDDI	512	3 - 2048
ATM / 155 ATM	512	0 - 2048

Following are examples of PCI adapter transmit queue sizes:

PCI Adapter Type	Default	Range
Ethernet	64	16 - 256
10/100 Ethernet	256, 512, or 2048	16 - 16384
Token-Ring	96, 512, or 2048	32 - 16384
FDDI	30 or 2048	3 - 16384
155 ATM	100 or 2048	0 - 16384

For adapters that provide hardware queue limits, changing these values will cause more real memory to be consumed on receives because of the associated control blocks and buffers associated with them. Therefore, raise these limits only if needed or for larger systems where the increase in memory use is negligible. For the software transmit queue limits, increasing these limits does not increase memory usage. It only allows packets to be queued that were already allocated by the higher layer protocols.

Receive Queues

Some adapters allow you to configure the number of resources used for receiving packets from the network. This might include the number of receive buffers (and even their size) or may be a receive queue parameter (which indirectly controls the number of receive buffers).

The receive resources may need to be increased to handle peak bursts on the network. The network interface device driver places incoming packets on a receive queue. If the receive queue is full, packets are dropped and lost, resulting in the sender needing to retransmit. The receive queue is tunable using the SMIT or **chdev** commands (see How to Change the Parameters). The maximum queue size is specified to each type of communication adapter (see Tuning MCA and PCI Adapters).

For the Micro Channel adapters and the PCI adapters, receive queue parameters typically control the number of receive buffers that are provided to the adapter for receiving input packets.

Device-Specific Buffers

AIX 4.1.4 and later support device-specific mbufs. This allows a driver to allocate its own private set of buffers and have them pre-setup for Direct Memory Access (DMA). This can provide additional performance because the overhead to set up the DMA mapping is done one time. Also, the adapter can allocate buffer sizes that are best suited to its MTU size. For example, ATM, High Performance Parallel Interface (HIPPI), and the SP switch support a 64 K MTU (packet) size. The maximum system mbuf size is 16 KB. By allowing the adapter to have 64 KB buffers, large 64 K writes from applications can be copied directly into the 64 KB buffers owned by the adapter, instead of copying them into multiple 16 K buffers (which has more overhead to allocate and free the extra buffers).

The adapters that support Device Specific mbufs are:

- MCA ATM
- MCA HIPPI
- Various SP high speed switch adapters

Device-specific buffers add an extra layer of complexity for the system administrator. The system administrator must use device-specific commands to view the statistics relating to the adapter's buffers and then change the adapter's parameters as necessary. If the statistics indicate that packets were discarded because not enough buffer resources were available, then those buffer sizes need to be increased.

Due to differences between drivers and the utilities used to alter these parameters, the utilities and parameters are not fully described here. The MCA ATM parameters are listed in Micro Channel Adapter (MCA). Use the **atmstat -d atm0** command to view the ATM statistics (substitute your ATM interface number as needed).

When to Increase the Receive/Transmit Queue Parameters

Following are some guidelines to help you determine when to increase the receive/transmit queue parameters:

1. When the CPU is much faster than the network and multiple applications may be using the same network. This would be common on a larger multi-processor system (SMP).
2. When running with large values for **tcp_sendspace** or **tcp_recvspace** as set in the **no** options or running applications that might use system calls to increase the TCP send and receive socket buffer

space. These large values can cause the CPU to send down large numbers of packets to the adapter, which will need to be queued. Procedures are similar for **udp_sendspace** and **udp_recvspace** for UDP applications.

3. When there is very bursty traffic.
4. A high-traffic load of small packets can consume more resources than a high traffic load of large buffers. Because large buffers take more time to send on the network. The packet rate will therefore be slower for larger packets.

Commands to Query and Change the Queue Parameters

Several status utilities can be used to show the transmit queue high-water limits and number of queue overflows. You can use the command **netstat -v**, or go directly to the adapter statistics utilities (**entstat** for Ethernet, **tokstat** for Token-Ring, **fdistat** for FDDI, **atmstat** for ATM, and so on).

For an **entstat** example output, see The entstat Command. Another method is to use the **netstat -i** utility. If it shows non-zero counts in the 0errs column for an interface, then this is typically the result of output queue overflows.

How to See the Settings

You can use the **lsattr -E -l adapter-name** command or you can use the SMIT command (**smitty commodev**) to show the adapter configuration.

Different adapters have different names for these variables. For example, they may be named **sw_txq_size**, **tx_que_size**, or **xmt_que_size** for the transmit queue parameter. The receive queue size and receive buffer pool parameters may be named **rec_que_size**, **rx_que_size**, or **rv_buf4k_min** for example.

Following is the output of a **lsattr -E -l atm0** command on an IBM PCI 155 Mbs ATM adapter. This output shows the **sw_txq_size** is set to 250 and the **rv_buf4K_min** receive buffers set to x30.

```
# lsattr -E -l atm0
dma_mem      0x400000    N/A                               False
regmem       0x1ff88000  Bus Memory address of Adapter Registers  False
virtmem      0x1ff90000  Bus Memory address of Adapter Virtual Memory  False
busintr      3           Bus Interrupt Level                 False
intr_priority 3          Interrupt Priority                   False
use_alt_addr no         Enable ALTERNATE ATM MAC address      True
alt_addr     0x0        ALTERNATE ATM MAC address (12 hex digits) True
sw_txq_size  250       Software Transmit Queue size         True
max_vc       1024      Maximum Number of VCs Needed         True
min_vc       32        Minimum Guaranteed VCs Supported     True
rv_buf4k_min 0x30      Minimum 4K-byte pre-mapped receive buffers True
interface_type 0        Sonet or SDH interface               True
adapter_clock 1         Provide SONET Clock                  True
uni_vers     auto_detect N/A                               True
```

Following is an example of a Micro Channel 10/100 Ethernet settings using the **lsattr -E -l ent0** command. This output shows the **tx_que_size** and **rx_que_size** both set to 256.

```
# lsattr -E -l ent0
bus_intr_lvl 11          Bus interrupt level                 False
intr_priority 3          Interrupt priority                   False
dma_bus_mem  0x7a0000    Address of bus memory used for DMA  False
bus_io_addr  0x2000     Bus I/O address                     False
dma_lvl      7           DMA arbitration level               False
tx_que_size  256       TRANSMIT queue size                 True
rx_que_size  256       RECEIVE queue size                   True
use_alt_addr no         Enable ALTERNATE ETHERNET address    True
alt_addr     0x         ALTERNATE ETHERNET address          True
media_speed  100_Full_Duplex Media Speed                           True
ip_gap       96         Inter-Packet Gap                     True
```

How to Change the Parameters

The following are some of the parameters that are user-configurable:

- Transmit Queue Size (**tx_que_size**)

The device driver supports a user-configurable transmit queue. This is the queue the adapter uses (not an extension of the adapter's queue). It is configurable among the values of 16, 32, 64, 128 and 256, with a default of 256.

Because of the configurable size of the adapter's hardware queue, the driver does not support a software queue.

- Receive Queue Size (**rx_que_size**)

The device driver supports a user-configurable receive queue. This is the queue the adapter uses (not an extension of the adapter's queue). It is configurable among the values of 16, 32, 64, 128 and 256, with a default of 256.

- Receive Buffer Pool Size (**rxbuf_pool_size**)

The device driver supports a user-configurable receive buffer pool size. The buffer is the number of preallocated mbufs for receiving packets. The minimum size of the buffer is the receive queue size and the maximum is 2 KB (the default value of 384).

- Media Speed (**media_speed**)

The device driver supports speeds of 10 (10 Mbps, half-duplex), 20 (10 Mbps, full-duplex), 100 (100 Mbps, half-duplex), 200 (100 Mbps, full-duplex), and auto-negotiate on twisted pair. On the AUI port, the device driver supports speeds of 10 (10 Mbps, half-duplex) and 20 (10 Mbps, full-duplex). The bayonet Niell-Concelman (BNC) port will only support 10 (10 Mbps, half-duplex). This attribute is user-configurable, with a default of auto-negotiate on twisted pair.

- Enable Alternate Address (**use_alt_addr**)

The device driver supports a configuration option to toggle use of an alternate network address. The values are yes and no, with a default of no. When this value is set to yes, the **alt_addr** parameter defines the address.

- Alternate Network Address (**alt_addr**)

For the network address, the device driver accepts the adapter's hardware address or a configured alternate network address. When the **use_alt_addr** configuration option is set to yes, this alternate address is used. Any valid individual address can be used, but a multicast address cannot be defined as a network address.

- Inter-Packet Gap (**ip_gap**)

The inter-packet gap (IPG) bit rate setting controls the aggressiveness of the adapter on the network. A smaller number will increase the aggressiveness of the adapter, while a larger number will decrease the aggressiveness (and increase the fairness) of the adapter. If the adapter statistics show a large number of collisions and deferrals, increase this number. Valid values range from 96 to 252, in increments of 4. The default value of 96 results in IPG of 9.6 microseconds for 10 Mb and 0.96 microseconds for 100 Mb media speeds. Each unit of bit rate introduces an IPG of 100 ns at 10 Mb and 10 ns at 100 Mb media speed.

To change any of the parameter values, do the following:

1. Detach the interface by running the following command:

```
# ifconfig en0 detach
```

where *en0* represents the adapter name.

2. Use SMIT to display the adapter settings. Select **Devices -> Communications -> adapter type -> Change/Show...**
3. Move the cursor to the field you want to change, and press F4 to see the minimum and maximum ranges for the field (or the specific set of sizes that are supported).
4. Select the appropriate size, and press Enter to update the ODM database.
5. Reattach the adapter by running the following command:

```
# ifconfig en0 hostname up
```

An alternative method to change these parameter values is to run the following command:

```
# chdev -l [ifname] -a [attribute-name]=newvalue
```

For example, to change the above **tx_que_size** on en0 to 128, use the following sequence of commands. Note that this driver only supports four different sizes, so it is better to use the SMIT command to see these values.

```
# ifconfig en0 detach
# chdev -l ent0 -a tx_que_size=128
# ifconfig en0 hostname up
```

Tuning MCA and PCI Adapters

The following information is provided to document the various adapter-tuning parameters. These parameters and values are for AIX 4.3.1 and are provided to aid you in understanding the various tuning parameters, or when a system is not available to view the parameters.

These parameter names, defaults, and range values were obtained from the ODM database. The comment field was obtained from the **lsattr -E -l interface-name** command.

The Notes field provides additional comments.

Micro Channel Adapter (MCA):

Feature Code: 2980
Ethernet High-Performance LAN Adapter (8ef5)

Parameter	Default	Range	Comment	Notes
xmt_que_size	512	20-2048	TRANSMIT queue size	SW TX queue
rec_que_size	30	20-150	RECEIVE queue size	See Note 1
rec_pool_size	37	16-64	RECEIVE buffer pool size	On Adapter

Feature Code: 2992
Ethernet High-Performance LAN Adapter (8f95)

Parameter	Default	Range	Comment	Notes
xmt_que_size	512	20-2048	TRANSMIT queue size	SW queue

Feature Code: 2994
IBM 10/100 Mbps Ethernet TX MCA Adapter (8f62)

Parameter	Default	Range	Comment	Notes
tx_que_size	64	16,32,64,128,256	TRANSMIT queue size	HW queue
rx_que_size	32	16,32,64,128,256	RECEIVE queue size	HW queue

Feature Code: 2970
Token-Ring High-Performance Adapter (8fc8)

Parameter	Default	Range	Comment	Notes
xmt_que_size	99	32-2048	TRANSMIT queue size	SW queue
rec_que_size	30	20-150	RECEIVE queue size	See Note 1

Feature Code: 2972
Token-Ring High-Performance Adapter (8fa2)

Parameter	Default	Range	Comment	Notes
-----------	---------	-------	---------	-------

```

-----
xmt_que_size 512      32-2048 TRANSMIT queue size      SW queue
rx_que_size  32       32-160  HARDWARE RECEIVE queue size HW queue

```

Feature Code: 2727
 FDDI Primary Card, Single Ring Fiber

Parameter	Default	Range	Comment	Notes
tx_que_size	512	3-2048	Transmit Queue Size (in mbufs)	
rcv_que_size	30	20-150	Receive Queue	See Note 1

Feature Code: 2984
 100 Mbps ATM Fiber Adapter (8f7f)

Parameter	Default	Range	Comment	Notes
sw_queue	512	0-2048	Software transmit queue len.	SW Queue
dma_bus_width	0x1000000	0x800000-0x40000000,0x100000	Amount of memory to map for DMA	See Note 3
max_sml_bufs	50	40-400	Maximum Small ATM mbufs	Max 256 byte buffers
max_med_bufs	100	40-1000	Maximum Medium ATM mbufs	Max 4KB buffers
max_lrg_bufs	300	75-1000	Maximum Large ATM mbufs	Max 8KB buffers See Note 2
max_hug_bufs	50	0-400	Maximum Huge ATM mbufs	Max 16KB buffers
max_spec_bufs	4	0-400	Maximum ATM MTB mbufs	Max of max_spec_buf size
spec_buf_size	64	32-1024	Max Transmit Block (MTB) size (kbytes)	
sml_highwater	20	10-200	Minimum Small ATM mbufs	Min 256 byte buffers
med_highwater	30	20-300	Minimum Medium ATM mbufs	Min 4KB buffers
lrg_highwater	70	65-400	Minimum Large ATM mbufs	Min 8KB buffers
hug_highwater	10	4-300	Minimum Huge ATM mbufs	Min 16KB buffers
spec_highwater	20	0-300	Minimum ATM MTB mbufs	Min 64KB buffers
best_peak_rate	1500	1-155000	Virtual Circuit Peak Segmentation Rate	

Feature Code: 2989
 155 Mbps ATM Fiber Adapter (8f67)

Parameter	Default	Range	Comment	Notes
(same as ATM 100 adapter above)				

Notes:

1. A software receive queue is provided only for compatibility with operating system version 3.2.x applications that use the network device driver interface to read packets directly from the driver. This queue limits how many input packets are queued for these applications to receive. This parameter is defined only if **bos.compat** is installed.
 This queue is not used by the typical TCP/IP stack.
2. MCA ATM: The receive side also uses the large (8 K) buffers. The receive logic only uses the 8 K buffers, so if this size runs low, it affects receive performance.
 The other buffers sizes are only for transmit buffers.
3. MCA ATM: If you need to increase the total number of buffers, you may need to change the **dma_bus_width** (= 0x1000000) parameter. DMA bus memory width controls the total amount of memory used for ATM buffers. Increase this parameter if you get an error while you are increasing the maximum buffers or high-water limits.

PCI Adapters:

Feature Code 2985
 IBM PCI Ethernet Adapter (22100020)

Parameter	Default	Range	Comment	Notes
-----------	---------	-------	---------	-------

tx_que_size	64	16,32,64,128,256	TRANSMIT queue size	HW Queues
rx_que_size	32	16,32,64,128,256	RECEIVE queue size	HW Queues

Feature Code 2968
IBM 10/100 Mbps Ethernet PCI Adapter (23100020)

Parameter	Default	Range	Comment	Notes
tx_que_size	256	16,32,64,128,256	TRANSMIT queue size	HW Queue Note 1
rx_que_size	256	16,32,64,128,256	RECEIVE queue size	HW Queue Note 2
rxbuf_pool_size	384	16-2048	# buffers in receive buffer pool	Dedicat. receive buffers Note 3

Feature Code: 2969
Gigabit Ethernet-SX PCI Adapter (14100401)

Parameter	Default	Range	Comment	Notes
tx_que_size	512	512-2048	Software Transmit Queue size	SW Queue
rx_que_size	512	512	Receive queue size	HW Queue
receive_proc	6	0-128	Minimum Receive Buffer descriptors	

Feature Code: 2986
3Com 3C905-TX-IBM Fast EtherLink XL NIC

Parameter	Default	Range	Comment	Notes
tx_wait_q_size	32	4-128	Driver TX Waiting Queue Size	HW Queues
rx_wait_q_size	32	4-128	Driver RX Waiting Queue Size	HW Queues

Feature Code: 2742
SysKonnnect PCI FDDI Adapter (48110040)

Parameter	Default	Range	Comment	Notes
tx_queue_size	30	3-250	Transmit Queue Size	SW Queue
RX_buffer_cnt	42	1-128	Receive frame count	Rcv buffer pool

Feature Code: 2979
IBM PCI Tokenring Adapter (14101800)

Parameter	Default	Range	Comment	Notes
xmt_que_size	96	32-2048	TRANSMIT queue size	SW Queue
rx_que_size	32	32-160	HARDWARE RECEIVE queue size	HW queue

Feature Code: 2979
IBM PCI Tokenring Adapter (14103e00)

Parameter	Default	Range	Comment	Notes
xmt_que_size	512	32-2048	TRANSMIT queue size	SW Queue
rx_que_size	64	32-512	RECEIVE queue size	HW Queue

Feature Code: 2988
IBM PCI 155 Mbps ATM Adapter (14107c00)

Parameter	Default	Range	Comment	Notes
-----------	---------	-------	---------	-------

```

-----
sw_txq_size   100      0-4096      Software Transmit Queue size   SW Queue
rv_buf4k_min  48 (0x30) 0-512 (x200) Minimum 4K-byte pre-mapped receive buffers

```

Notes on the IBM 10/100 Mbps Ethernet PCI Adapter:

1. Prior to AIX 4.3.2, default **tx_queue_size** was 64.
2. Prior to AIX 4.3.2, default **rx_que_size** was 32.
3. In AIX 4.3.2 and later, the driver added a new parameter to control the number of buffers dedicated to receiving packets.

Enabling Thread Usage on LAN Adapters (dog threads)

Drivers, by default, call IP directly, which calls up the protocol stack to the socket level while running on the interrupt level. This minimizes instruction path length, but increases the interrupt hold time. On an SMP system, a single CPU can become the bottleneck for receiving packets from a fast adapter. By enabling the *dog threads*, the driver queues the incoming packet to the thread and the thread handles calling IP, TCP, and the socket code. The thread can run on other CPUs which may be idle. Enabling the dog threads can increase capacity of the system in some cases.

Note: This feature is not supported on uniprocessors, because it would only add path length and slow down performance.

This is a feature for the input side (receive) of LAN adapters. It can be configured at the interface level with the **ifconfig** command (**ifconfig interface thread** or **ifconfig interface hostname up thread**).

To disable the feature, use the **ifconfig interface -thread** command.

Guidelines when considering using dog threads are as follows:

- More CPUs than adapters need to be installed. Typically, at least two times more CPUs than adapters are recommended.
- Systems with faster CPUs benefit less. Machines with slower CPU speed may be helped the most.
- This feature is most likely to enhance performance when there is high input packet rate. It will enhance performance more on MTU 1500 compared to MTU 9000 (jumbo frames) on Gigabit as the packet rate will be higher on small MTU networks.

The dog threads run best when they find more work on their queue and do not have to go back to sleep (waiting for input). This saves the overhead of the driver waking up the thread and the system dispatching the thread.

- The dog threads can also reduce the amount of time a specific CPU spends with interrupts masked. This can release a CPU to resume typical user-level work sooner.
- The dog threads can also reduce performance by about 10 percent if the packet rate is not fast enough to allow the thread to keep running. The 10 percent is an average amount of increased CPU overhead needed to schedule and dispatch the threads.

Tuning TCP Maximum Segment Size

The TCP protocol includes a mechanism for both ends of a connection to negotiate the maximum segment size (MSS) to be used over the connection. Each end uses the **OPTIONS** field in the TCP header to advertise a proposed MSS. The MSS that is chosen is the smaller of the values provided by the two ends.

The purpose of this negotiation is to avoid the delays and throughput reductions caused by fragmentation of the packets when they pass through routers or gateways and reassembly at the destination host.

The value of MSS advertised by the TCP software during connection setup depends on whether the other end is a local system on the same physical network (that is, the systems have the same network number) or whether it is on a different (remote) network.

Local Network

If the other end of the connection is local, the MSS advertised by TCP is based on the MTU (maximum transfer unit) of the local network interface, as follows:

TCP MSS = MTU - TCP header size - IP header size.

Because this is the largest possible MSS that can be accommodated without IP fragmentation, this value is inherently optimal, so no MSS-tuning is required for local networks.

Remote Network

When the other end of the connection is on a remote network, this operating system's TCP defaults to advertising an MSS of 512 bytes. This conservative value is based on a requirement that all IP routers support an MTU of at least 576 bytes.

The optimal MSS for remote networks is based on the smallest MTU of the intervening networks in the route between source and destination. In general, this is a dynamic quantity and could only be ascertained by some form of path MTU discovery. The TCP protocol, by default, does not provide a mechanism for doing path MTU discovery, which is why a conservative MSS value is the default. However, it is possible to enable the TCP PMTU discovery by using the following command:

```
# no -o tcp_pmtu_discover=1
```

MTU path discovery was added to AIX 4.2.1, but the default is off. With AIX 4.3.3 and later, the default is on.

A typical side effect of this setting is to see the routing table increasing (one more entry per each active TCP connection). The **no** option **route_expire** should be set to a non-zero value, in order to have any unused cached route entry removed from the table, after **route_expire** time of inactivity.

While the conservative default is appropriate in the general Internet, it can be unnecessarily restrictive for private Intranets within an administrative domain. In such an environment, MTU sizes of the component physical networks are known, and the minimum MTU and optimal MSS can be determined by the administrator. The operating system provides several ways in which TCP can be persuaded to use this optimal MSS. Both source and destination hosts must support these features. In a heterogeneous, multi-vendor environment, the availability of the feature on both systems can determine the choice of solution.

Static Routes: The default MSS of 512 can be overridden by specifying a static route to a specific remote network. Use the **-mtu** option of the **route** command to specify the MTU to that network. In this case, you would specify the actual minimum MTU of the route, rather than calculating an MSS value.

In a small, stable environment, this method allows precise control of MSS on a network-by-network basis. The disadvantages of this approach are as follows:

- It does not work with dynamic routing.
- It becomes impractical when the number of remote networks increases.
- Static routes must be set at both ends to ensure that both ends negotiate with a larger-than-default MSS.

When to Use the `tcp_mssdfmt` Option of the `no` Command: This parameter is used to set the maximum packet size for communication with remote networks. However, only one value can be set even if there are several adapters with different MTU sizes. The default value of 512 that TCP uses for remote networks can be changed via the **no** command. This change is a systemwide change.

To override the MSS default specify a value that is the minimum MTU value less 40 to allow for the typical length of the TCP and IP headers.

The size is the same as the MTU for communication across a local network with one exception: the `tcp_mssdflt` size is only for the size of the data in a packet. Reduce the `tcp_mssdflt` for the size of any headers so that you send full packets instead of a full packet and a fragment. Calculate this as follows:

MTU of interface - TCP header size - IP header size - rfc1323 header size

which is:

MTU - 20 - 20 - 12, or MTU - 52

Limiting data to (MTU - 52) bytes ensures that, where possible, only full packets will be sent.

In an environment with a larger-than-default MTU, this method has the advantage in that the MSS does not need to be set on a per-network basis. The disadvantages are as follows:

- Increasing the default can lead to IP router fragmentation if the destination is on a network that is truly remote and the MTUs of the intervening networks are not known.
- The `tcp_mssdflt` parameter must be set to the same value on the destination host.

Subnetting and the `subnetsarelocal` Option of the `no` Command: Several physical networks can be made to share the same network number by subnetting. The `no` option `subnetsarelocal` specifies, on a systemwide basis, whether subnets are to be considered local or remote networks. With the command `no -o subnetsarelocal=1` (the default), Host A on subnet 1 considers Host B on subnet 2 to be on the same physical network.

The consequence is that when Host A and Host B establish a connection, they negotiate the MSS assuming they are on the same network. Each host advertises an MSS based on the MTU of its network interface, usually leading to an optimal MSS being chosen.

The advantages to this approach are as follows:

- It does not require any static bindings; MSS is automatically negotiated.
- It does not disable or override the TCP MSS negotiation, so that small differences in the MTU between adjacent subnets can be handled appropriately.

The disadvantages to this approach are as follows:

- Potential IP router fragmentation when two high-MTU networks are linked through a lower-MTU network. The following figure illustrates this problem.

Figure 25. Inter-Subnet Fragmentation. This illustration shows a data path from Host A, through an FDDI with an MTU=4352, through Router 1, to the Ethernet with an MTU=1500. From there it goes to Router 2 and another FDDI with an MTU=4352 and out to Host B. An explanation of how fragmentation occurs in this example is described in the text immediately following the illustration.

- In this scenario, Hosts A and B would establish a connection based on a common MTU of 4352. A packet going from A to B would be fragmented by Router 1 and defragmented by Router 2. The reverse would occur going from B to A.
- Source and destination must both consider subnets to be local.

UDP Socket Buffer Tuning

UDP is a datagram protocol. Being a datagram, the entire message (datagram) must be copied into the kernel on a send operation as one atomic operation. The maximum amount of data that UDP can send at

one time is limited by the size of the memory buffer assigned to a specific UDP socket, and the maximum packet size that the IP layer can handle in each packet.

udp_sendspace

Set this parameter to 65536, because any value greater than 65536 is ineffective. Because UDP transmits a packet as soon as it gets any data, and because IP has an upper limit of 65536 bytes per packet, anything beyond 65536 runs the small risk of being discarded by IP. The IP protocol will fragment the datagram into smaller packets if needed, based on the MTU size of the interface the packet will be sent on. For example, sending an 8 K datagram, IP would fragment this into 1500 byte packets if sent over Ethernet. Because UDP does not implement any flow control, all packets given to UDP are passed to IP (where they may be fragmented) and then placed directly on the device drivers transmit queue.

udp_recvspace

On the receive side, the incoming datagram (or fragment if the datagram is larger than the MTU size) will first be received into a buffer by the device driver. This will typically go into a buffer that is large enough to hold the largest possible packet from this device.

The setting of **udp_recvspace** is harder to compute because it varies by network adapter type, UDP sizes, and number of datagrams queued to the socket. Set the **udp_recvspace** larger rather than smaller, because packets will be discarded if it is too small.

For example, Ethernet might use 2 K receive buffers. Even if the incoming packet is maximum MTU size of 1500 bytes, it will only use 73 percent of the buffer. IP will queue the incoming fragments until a full UDP datagram is received. It will then be passed to UDP. UDP will put the incoming datagram on the receiver's socket. However, if the total buffer space in use on this socket exceeds **udp_recvspace**, then the entire datagram will be discarded. This is indicated in the output of the **netstat -s** command as dropped due to full socket buffers errors.

Because the communication subsystem accounts for buffers used, and not the contents of the buffers, you must account for this when setting **udp_recvspace**. In the above example, the 8 K datagram would be fragmented into 6 packets which would use 6 receive buffers. These will be 2048 byte buffers for Ethernet. So, the total amount of socket buffer consumed by this one 8 K datagram is as follows:

$6 * 2048 = 12,288$ bytes

Thus, you can see that the **udp_recvspace** must be adjusted higher depending on how efficient the incoming buffering is. This will vary by datagram size and by device driver. Sending a 64 byte datagram would consume a 2 K buffer for each 64 byte datagram.

Then, you must account for the number of datagrams that may be queued onto this one socket. For example, NFS server receives UDP packets at one well-known socket from all clients. If the queue depth of this socket could be 30 packets, then you would use $30 * 12,288 = 368,640$ for the **udp_recvspace** if NFS is using 8 K datagrams. NFS Version 3 allows up to 32K datagrams.

A suggested starting value for **udp_recvspace** is 10 times the value of **udp_sendspace**, because UDP may not be able to pass a packet to the application before another one arrives. Also, several nodes can send to one node at the same time. To provide some staging space, this size is set to allow 10 packets to be staged before subsequent packets are discarded. For large parallel applications using UDP, the value may have to be increased.

Note: The value of **sb_max**, which specifies the maximum socket buffer size for any socket buffer, should be at least twice the size of the largest of the UDP and TCP send and receive buffers.

TCP Socket Buffer Tuning

The following table shows some suggested *minimum* sizes for socket buffers based on the type of adapter and the MTU size. Note that setting these values too high can hurt performance. In addition, there is the *Nagle Black hole* problem that can cause very low throughput for large MTU adapters, such as ATM if the

TCP send and receive space parameters are not chosen correctly.

Device	Speed	MTU	tcp_sendspace	tcp_recvspace	sb_max	rfc1323
Ethernet	10 Mbit	1500	16384	16384	32768	0
Ethernet	100 Mbit	1500	16384	16384	32768	0
Ethernet	Gigabit	1500	65535	16384	131072	0
Ethernet	Gigabit	9000	131072	65535 (Note 1)	262144	0
Ethernet	Gigabit	9000	131072	92160 (Note 1)	262144	1
ATM	155 Mbit	1500	16384	16384	131072	0
ATM	155 Mbit	9180	65535	65535 (Note 2)	131072	0
ATM	155 Mbit	65527	655360	655360 (Note 3)	1310720	1
FDDI	100 Mbit	4352	45056	45056	90012	0

Note 1:

In the case of Gigabit Ethernet with a 9000 byte MTU, the performance was the same for both given sets of buffer sizes.

Note 2:

Certain combinations of TCP send and receive space will result in very low throughput (1 Mbit or less). This problem is described in detail in *How a Large ATM MTU Causes Deadlocks in TCP Data Transfers*, IEEE/ACM Transactions on Networking, Vol. 3, No.4 August 1995 and *TCP Buffering and Performance over an ATM Network*, Internetworking: Research and Experience, Vol. 6 1-13, 1995.

To avoid this problem, set the **tcp_sendspace** to a minimum of 3 times the MTU size or equal or larger than the receivers **tcp_recvspace**. For example, on ATM with MTU 9180, a **tcp_sendspace** of 16384 and a **tcp_recvspace** of 32768 or 65536 resulted in very poor performance. However, setting both to 65536 resulted in excellent performance. Also, setting both equal to 16384 resulted in acceptable performance (the equal or larger rule).

Note 3:

TCP has only a 16-bit value to use for its window size. This translates to a maximum window size of 65536 bytes. For adapters that have large MTU sizes (32 K or 64 K for example), TCP streaming performance may be very poor. For example, on a device with a 64 K MTU size, and with a **tcp_recvspace** set to 64 K, TCP can only send one packet and then its window will close. It must wait for an ACK back from the receiver before it can send again. This problem can be solved in two ways:

One option is to enable **rfc1323**. This option enhances TCP and allows it to overcome the 16 bit limit so that it can use a window size larger than 64 Kb. You can then set the **tcp_recvspace** to a large value such as 10 times the MTU size which will allow TCP to stream data and give good performance.

The second option is to reduce the MTU size of the adapter. For example, use the command **ifconfig at0 mtu 16384** to set the ATM MTU size to 16 K. This will cause TCP to compute a smaller MSS. With a 16 K MTU size, it could still send 4 packets for a 64 K window size.

Following are some general guidelines:

- Set the TCP send/rcv space to at least 10 times the MTU size.
- MTU sizes above 16 K should use **rfc1323=1** to allow larger TCP recvspace values.
- For high-speed adapters, larger TCP send/receive space values help performance.
- The window size is the receiver's window size; therefore, **rfc1323** affects only the receiver.

- For the Gigabit Ethernet adapter increase the **tcp_sendspace**. If the application gets blocked and is put to sleep due to a small **tcp_sendspace**, there is too much latency on wake up and sending the packets again to keep the adapter busy.

The **ftp** and **rcp** commands are examples of TCP applications that benefit from tuning the **tcp_sendspace** and **tcp_recvspace** variables.

tcp_sendspace

TCP send buffer size can limit how much data the application can send before the application is put to sleep. The TCP socket send buffer is used to buffer the application data in the kernel using mbufs/clusters before it is sent beyond the socket and TCP layer. The default size of this buffer is specified by the parameter **tcp_sendspace**, but you can use the **setsockopt()** subroutine to override it.

If the amount of data that the application wants to send is smaller than the send buffer size and also smaller than the maximum segment size and if **TCP_NODELAY** is not set, then TCP will delay up to 200 ms, until enough data exists to fill the send buffer or the amount of data is greater than or equal to the maximum segment size, before transmitting the packets.

If **TCP_NODELAY** is set, then the data is sent immediately (useful for request/response type of applications). If the send buffer size is less than or equal to the maximum segment size (ATM and SP switches can have 64 K MTUs), then the application's data will be sent immediately and the application must wait for an ACK before sending another packet (this prevents TCP streaming and could reduce throughput).

Note: To maintain a steady stream of packets, increase the socket send buffer size so that it is greater than the MTU (3-10 times the MTU size could be used as a starting point).

If an application does nonblocking I/O (specified **O_NDELAY** or **O_NONBLOCK** on the socket), then if the send buffer fills up, the application will return with an **EWOULDBLOCK/EAGAIN** error rather than being put to sleep. Applications must be coded to handle this error (suggested solution is to sleep for a short while and try to send again).

When you are changing send/rcv space values, in some cases you must stop/restart the **inetd** process as follows:

```
# stopsrc -s inetd; startsrc -s inetd
```

tcp_recvspace

TCP receive-buffer size limits how much data the receiving system can buffer before the application reads the data. The TCP receive buffer is used to accommodate incoming data. When the data is read by the TCP layer, TCP can send back an acknowledgment (ACK) for that packet immediately or it can delay before sending the ACK. Also, TCP tries to piggyback the ACK if a data packet was being sent back anyway. If multiple packets are coming in and can be stored in the receive buffer, TCP can acknowledge all of these packets with one ACK. Along with the ACK, TCP returns a window advertisement to the sending system telling it how much room remains in the receive buffer. If not enough room remains, the sender will be blocked until the application has read the data. Smaller values will cause the sender to block more. The size of the TCP receive buffer can be set using the **setsockopt()** subroutine or by the **tcp_recvspace** parameter.

rfc1323

The TCP window size by default is limited to 65536 bytes (64 K) but can be set higher if **rfc1323** is set to 1. If you are setting **tcp_recvspace** to greater than 65536, set **rfc1323=1** on each side of the connection. Without having **rfc1323** set on both sides, the effective value for **tcp_recvspace** will be 65536.

If you are sending data through adapters that have large MTU sizes (32 K or 64 K for example), TCP streaming performance may not be optimal because the packet or packets will be sent and the sender will have to wait for an acknowledgment. By enabling the **rfc1323** option using the command **no -o rfc1323=1**, TCP's window size can be set as high as 4 GB. However, on adapters that have 64 K or larger MTUs,

TCP streaming performance can be degraded if the receive buffer can only hold 64 K. If the receiving machine does not support **rfc1323**, then reducing the MTU size is one way to enhance streaming performance.

After setting the **rfc1323** option to 1, you can increase the **tcp_recvspace** parameter to something much larger, such as 10 times the size of the MTU.

sb_max

This parameter controls how much buffer space is consumed by buffers that are queued to a sender's socket or to a receiver's socket. The system accounts for socket buffers used based on the size of the buffer, not on the contents of the buffer.

If a device driver puts 100 bytes of data into a 2048-byte buffer, then the system considers 2048 bytes of socket buffer space to be used. It is common for device drivers to receive buffers into a buffer that is large enough to receive the adapters maximum size packet. This often results in wasted buffer space but it would require more CPU cycles to copy the data to smaller buffers.

Because there are so many different network device drivers, increase the **sb_max** value much higher rather than making it the same as the largest TCP or UDP socket buffer size parameters. After the total number of mbufs/clusters on the socket reaches the **sb_max** limit, no additional buffers can be queued to the socket until the application has read the data.

Note: When you are setting buffer size parameters to larger than 64 K, you must also increase the value of **sb_max**, which specifies the maximum socket buffer size for any socket buffer.

One guideline would be to set it to twice as large as the largest TCP or UDP receive space.

Interface-Specific Network Options (ISNO)

In AIX 4.3.3, a feature called Interface-Specific Network Options (ISNO) was introduced that allows IP network interfaces to be custom-tuned for the best performance. Values set for an individual interface take precedence over the systemwide values set with the **no** command. The feature is enabled (the default) or disabled for the whole system with the **no** command **use_isno** option. This single-point ISNO disable option is included as a diagnostic tool to eliminate potential tuning errors if the system administrator needs to isolate performance problems.

Programmers and performance analysts should note that the ISNO values will not show up in the socket (meaning they cannot be read by the **getsockopt()** system call) until *after* the TCP connection is made. The interface this socket will actually be using is not known until the connection is complete, so the socket reflects the system defaults from the **no** command. After the connection is accepted, ISNO values are put into the socket.

The following five parameters have been added for each supported network interface:

- **rfc1323**
- **tcp_nodelay**
- **tcp_sendspace**
- **tcp_recvspace**
- **tcp_msdfit**

When set for a specific interface, these values override the corresponding **no** option values set for the system. These parameters are available for all of the mainstream TCP/IP interfaces (Token-Ring, FDDI, 10/100 Ethernet, and Gigabit Ethernet), except the **css#** IP interface on the SP switch. As a simple workaround, SP switch users can set the tuning options appropriate for the switch using the systemwide **no** command, then use the ISNOs to set the values needed for the other system interfaces. ATM is supported and works correctly with AIX 4.3.3 (a software update is needed) and later.

These options are set for the TCP/IP interface (such as en0 or tr0), and not the network adapter (ent0 or tok0).

The five new ISNO parameters cannot be displayed or changed using SMIT. Following are commands that can be used first to verify system and interface support and then to set and verify the new values.

- Make sure the **use_isno** option is enabled by using the following command:

```
# no -a | grep isno
use_isno = 1
```

- Make sure the interface supports the five new ISNOs by using the **lsattr -EI** command:

```
# lsattr -E -l en0 -H
attribute      value description                                user_settable
:
rfc1323        N/A                                           True
tcp_nodelay    N/A                                           True
tcp_sendspace  N/A                                           True
tcp_recvspace  N/A                                           True
tcp_mssdfmt    N/A                                           True
```

- Set the interface-specific values, using either the **ifconfig** or **chdev** command. The **ifconfig** command sets values temporarily (best used for testing). The **chdev** command alters the ODM, so custom values return after system reboots.

For example, to set the **tcp_recvspace** and **tcp_sendspace** to 64K and enable **tcp_nodelay**, use one of the following methods:

```
# ifconfig en0 tcp_recvspace 65536 tcp_sendspace 65536 tcp_nodelay 1
```

OR

```
# chdev -l en0 -a tcp_recvspace=65536 -a tcp_sendspace=65536 -a tcp_nodelay=1
```

- Verify the settings using the **ifconfig** or **lsattr** command:

```
# ifconfig en0
en0: flags=e080863<UP,BROADCAST,NOTRAILERS,RUNNING,SIMPLEX,MULTICAST,GRUPT,64BIT>
      inet 9.19.161.100 netmask 0xffffffff broadcast 9.19.161.255
      tcp_sendspace 65536 tcp_recvspace 65536 tcp_nodelay 1
```

OR

```
# lsattr -EI en0
rfc1323        N/A                                           True
tcp_nodelay    1      N/A                                           True
tcp_sendspace 65536  N/A                                           True
tcp_recvspace 65536  N/A                                           True
tcp_mssdfmt    N/A                                           True
```

IP Protocol Performance Tuning Recommendations

At the IP layer, the only tunable parameter is **ipqmaxlen**, which controls the length of the IP input queue discussed in IP Layer. In AIX Version 4, in general, interfaces do not do queuing. Packets can arrive very quickly and overrun the IP input queue. You can use the **netstat -s** or **netstat -p ip** command to view an overflow counter (ipintrq overflows).

If the number returned is greater than 0, overflows have occurred. Use the **no** command to set the maximum length of this queue. For example:

```
# no -o ipqmaxlen=100
```

This example allows 100 packets to be queued up. The exact value to use is determined by the maximum burst rate received. If this cannot be determined, using the number of overflows can help determine what the increase should be. No additional memory is used by increasing the queue length. However, an increase may result in more time spent in the off-level interrupt handler, because IP will have more packets to process on its input queue. This could adversely affect processes needing CPU time. The

tradeoff is reduced packet-dropping versus CPU availability for other processing. It is best to increase **ipqmaxlen** by moderate increments if the tradeoff is a concern in your environment.

Ethernet Performance Tuning Recommendations

Ethernet is one of the contributors to the "least common denominator" algorithm of MTU choice. If a configuration includes Ethernets and other LANs, and there is extensive traffic among them, the MTUs of all of the LANs may need to be set to 1500 bytes to avoid fragmentation when data enters an Ethernet.

Following are some guidelines:

- Do not change the default (and maximum) MTU of 1500 bytes.
- Set the application block size in multiples of 4096 bytes.
- Keep socket space settings at the default values.
- If the workload includes extensive use of services that use UDP, such as NFS or RPC, increase **sb_max** to allow for the fact that each 1500-byte MTU uses a 4096-byte buffer.

Token-Ring (4 MB) Performance Tuning Recommendations

The default MTU of 1492 bytes is appropriate for Token-Rings that interconnect to Ethernets or to heterogeneous networks in which the minimum MTU is not known. Following are some guidelines:

- Unless the LAN has extensive traffic to outside networks, raise the MTU to the maximum of 3900 bytes.
- Application block size should be in multiples of 4096 bytes.
- Socket space settings can be left at the default values.
- If the workload includes extensive use of services that use UDP, such as NFS or RPC, increase **sb_max** to allow for the fact that each 1492-byte MTU uses a 4096-byte buffer.

Token-Ring (16 MB) Performance Tuning Recommendations

The default MTU of 1492 bytes is appropriate for Token-Rings that interconnect to Ethernets or to heterogeneous networks in which the minimum MTU is not known. Following are some guidelines:

- Unless the LAN has extensive traffic to outside networks, raise the MTU to 8500 bytes. This allows NFS 8 KB packets to fit in one MTU. Further increasing the MTU to the maximum of 17000 bytes seldom results in corresponding throughput improvement.
- Application block size should be in multiples of 4096 bytes.
- Socket space settings can be left at the default values.
- If the workload includes extensive use of services that use UDP, such as NFS or RPC, and the MTU must be left at the default because of interconnections, increase **sb_max** to allow for the fact that each 1492-byte MTU uses a 4096-byte buffer.

FDDI Performance Tuning Recommendations

Despite the comparatively low MTU, this high-speed medium benefits from substantial increases in socket buffer size. Following are some guidelines:

- Unless the LAN has extensive traffic to outside networks, the default MTU of 4352 bytes should be retained.
- Where possible, an application using TCP should write multiples of 4096 bytes at a time (preferably 8 KB or 16 KB) for maximum throughput.
- Use **no -o *_space=NewSize** to set the TCP and UDP socket send and receive space defaults to *NewSize* bytes. *NewSize* should be at least 57344 bytes (56 KB).
- Use **no -o sb_max=(2*NewSize)** to increase the maximum number of socket buffer space.
- For RS/6000 Model *90 or faster, use **no -o rfc1323=1** to allow socket buffer sizes to be set to more than 65536. Then use the previous procedure with *NewSize* of at least 128 KB.

ATM Performance Tuning Recommendations

Following are some guidelines:

- Unless the LAN has extensive traffic to outside networks, retain the default MTU of 9180 bytes. Where possible, an application using TCP should write multiples of 4096 bytes at a time (preferably 8 KB or 16 KB) for maximum throughput.
- Use **no -o *_space=NewSize** to set the TCP and UDP socket send and receive space defaults to *NewSize* bytes. *NewSize* should be at least 57344 bytes (56 KB).
- Use **no -o sb_max=(2*NewSize)** to increase the maximum number of socket buffer space.
- For RS/6000 Model *90 or faster, use **no -o rfc1323=1** to allow socket buffer sizes to be set to more than 65536. Then use the previous procedure with *NewSize* of at least 128 KB.

SOCC Performance Tuning Recommendations

Following are some guidelines:

- The default MTU 61428 bytes should not be changed.
- Where possible, an application using TCP should write 28672 bytes (28 KB) at a time for maximum throughput.
- Set TCP and UDP socket send and receive space defaults to 57344 bytes.

HIPPI Performance Tuning Recommendations

Following are some guidelines:

- The default MTU of 65536 bytes should not be changed.
- Where possible, an application using TCP should write 65536 bytes at a time for maximum throughput.
- Set **sb_max** to a value greater than 2 * 655360.
- TCP and UDP socket send and receive space defaults should be set to 655360 bytes. Use **no -o rfc1323=1** to allow socket buffer sizes to be set to more than 65536.

Tuning mbuf Pool Performance

The network subsystem uses a memory management facility that revolves around a data structure called an mbuf. Mbufs are mostly used to store data for incoming and outbound network traffic. Having mbuf pools of the right size can have a very positive effect on network performance. If the mbuf pools are configured incorrectly, both network and system performance can suffer. In AIX Version 4, the mbuf parameters are automatically tuned based on the system configuration, particularly the number of communications adapters, and network requirements.

Overview of the mbuf Management Facility

The mbuf management facility controls different buffer sizes that can range from 32 bytes up to 16384 bytes. The pools are created from system memory by making an allocation request to the Virtual Memory Manager (VMM). The pools consist of pinned pieces of kernel virtual memory in which they always reside in physical memory and are never paged out. The result is that the real memory available for paging in application programs and data has been decreased by the amount that the mbuf pools have been increased.

The network memory pool is split evenly among each processor. Each sub-pool is then split up into buckets of 32-16384 bytes. Each bucket can borrow memory from other buckets on the same processor but a processor cannot borrow memory from another processor's network memory pool. When a network service needs to transport data, it can call a kernel service such as **m_get()** to obtain a memory buffer. If the buffer is already available and pinned, it can get it immediately. If the upper limit has not been reached and the buffer is not pinned, then a buffer is allocated and pinned. Once pinned, the memory stays pinned but can be freed back to the network pool. If the number of free buffers reaches a high-water mark, then a certain number is unpinned and given back to the system for general use. This unpinning is done by the

netm() kernel process. The caller of the **m_get()** subroutine can specify whether to wait for a network memory buffer. If **M_DONTWAIT** is specified and no pinned buffers are available at that time, a failed counter is incremented. If **M_WAIT** is specified, the process is put to sleep until the buffer can be allocated and pinned.

Tuning Network Memory

Use the command **netstat -m** to detect shortages of network memory (mbufs/clusters).

An upper limit is placed on how much of RAM can be used for network memory. You can tune this parameter by setting **maxmbuf** or **thewall**. The unit of **thewall** is in 1 KB, so that 16384 indicates 16 MB of RAM.

The default value for **thewall** in operating system version

- 4.2.1 is 1/8 of RAM or 16384 (16 MB), whichever is smaller
- 4.3.0 is 1/8 of RAM or 131072 (128 MB), whichever is smaller
- 4.3.1 is 1/2 of RAM or 131072 (128 MB), whichever is smaller
- 4.3.2 and later is 1/2 of RAM or 1048576 (1 GB), whichever is smaller

The maximum value of **thewall** is 64 MB prior to operating system version 4.3.0, 128 MB in operating system version 4.3.0 and version 4.3.1, and 1 GB in AIX 4.3.2 and higher (systems that are not Common Hardware Reference Platform (CHRP) are limited to 256 MB).

The value of **maxmbuf** is also used to limit how much real memory can be used by the communications subsystem. You can view this by running the command **lsattr -E -l sys0**. In AIX 4.2 and later, if **maxmbuf** is greater than 0 (can be changed using the **chdev** or **smitty** commands), the **maxmbuf** value is used regardless of the value of **thewall**. Prior to AIX 4.2, the upper limit on mbufs is the higher value of **maxmbuf** or **thewall**.

In AIX 4.2 and later, **maxmbuf** is set to 0. The value of 0 indicates that the system default (**thewall**) should be used.

The limit on network memory (**thewall** or **maxmbuf**) is also used to limit how much memory can be used for streams. The tunable parameter called **strthresh** (default value of 85 percent of **thewall/maxmbuf**) specifies that once the total amount of allocated memory has reached 85 percent, no more memory can be given to STREAMS.

Similarly, another threshold called **sockthresh** (also defaults to 85 percent) specifies that once the total amount of allocated memory has reached 85 percent of **thewall/maxmbuf**, no new socket connections can occur (the **socket()** and **socketpair()** system calls return with **ENOBUFS**). Use the **no** command to tune these thresholds.

Tuning Asynchronous Connections for High-Speed Transfers

Async ports permit the connection to a computer or optional devices such as terminals, printers, fax machines, and modems. Async ports are provided by adapter devices such as the 8-, 16-, or 64-port IBM adapters or the 128-port Digiboard adapter, which reside on the Micro Channel and provide multiple asynchronous connections, typically RS232 or RS422. Many adapters, such as the three IBM async adapters mentioned above, were originally designed for servicing terminals and printers, and so are optimized for output (sends). Input processing (receives) is not as well optimized, perhaps because the assumption was once made that users could not type very fast. This is not a great concern when data transmission is slow and irregular, as with keyboard input. It becomes a problem with raw-mode applications, where massive chunks of input are transmitted by other computers and by devices such as fax machines. In raw-mode processing, data is treated as a continuous stream; input bytes are not assembled into lines, and erase and kill processing are disabled.

Async Port Tuning Techniques

While some adapters have inherent limitations, the guidelines and techniques described here can provide better performance from these adapters for raw-mode transfers.

A shell script containing appropriate **stty** commands to implement most of the following tuning techniques is given at the end of the section.

- For input processing, using the **echo** option is expensive, as it increases the time per character. Character echo is useful for canonical user input but is probably not necessary for most raw-mode applications. Example:

```
# stty -echo < /dev/tty
```
- Increase the value of the **vmin** variable for each TTY from the default of 4. The **vmin** variable value is the minimum number of bytes that should be received when the read is successful. The value chosen for the **vmin** variable should be the lesser of the application data-block size or 255 (the maximum allowed). If the application block size is variable or unknown, **vmin** should be set to 255. Setting the **vmin** variable to 255 will result in fewer read executions and will reduce CPU utilization by 15 to 20 percent for file-transfer programs.
- Except on the 128-port adapter, set **vtime** > 0 to prevent an indefinite block on read. If the **vtime** variable is set to zero on the 128-port adapter, POSIX line-discipline processing will be offloaded to the adapter hardware, significantly reducing CPU processing.
- For raw-mode sends where output translations are not needed, turn off the **opost** option in the POSIX line discipline. This will help the CPU performance by reducing the output path length. For file-transfer applications, which move large amounts of data on TTY lines, this can reduce CPU utilization by 3 times. Example:

```
# stty -opost < /dev/tty
```
- Because the 64-port adapter is prone to unpredictable data overruns at higher baud rates when XON/XOFF is used for pacing, avoid the risk of losing data by using RTS/CTS hardware pacing instead.
- Because the 64-port-adapter concentrator boxes have a limited bandwidth and saturate at higher baud rates, adding more ports to a saturated concentrator will decrease the performance of all ports connected. Instead, add another concentrator and continue until it is saturated or you have run out of CPU.

Also, concentrator saturation is a concern because, if the concentrator box approaches overload, no additional throughput is accepted. The effective baud rate is lowered, and there is a noticeable slowdown in work.

Shell Script **fastport.sh** for Fast File Transfers

The **fastport.sh** script is intended to condition a TTY port for fast file transfers in raw mode; for example, when a fax machine is to be connected. Using the script may improve CPU performance by a factor of 3 at 38,400 baud. The **fastport.sh** script is not intended for the canonical processing that is used when interacting with a user at an async terminal, because canonical processing cannot be easily buffered. The bandwidth of the canonical read is too small for the fast-port settings to make a perceptible difference.

Any TTY port can be configured as a fast port. The improved performance is the result of reducing the number of interrupts to the CPU during the read cycle on a given TTY line. To configure a TTY port as a fast port, do the following:

1. Create a TTY for the port using the command **smitty** -> Devices -> TTY -> Add a TTY), with **Enable LOGIN=disable** and **BAUD rate=38,400**.
2. Create the Korn shell script named **fastport.sh**, as follows:

```
#####  
#  
#           Configures a fastport for "raw" async I/O.  
#  
#####
```

```

set -x
sync;sync
i=$1
if [ $i -le 100 ]
then
# for the native async ports and the 8-, 16-, and 64-port adapters
# set vmin=255 and vtime=0.5 secs with the following stty
stty -g </dev/tty$i |awk ' BEGIN { FS=":";OFS=":" }
{ $5="ff";$6=5;print $0 } ' >foo
# for a 128-port adapter, remove the preceding stty, then
# uncomment and use the
# following stty instead to
# set vmin=255 and vtime=0 to offload line discipline processing
# stty -g </dev/tty$i |awk ' BEGIN { FS=":";OFS=":" }
# { $5="ff";$6=0;print $0 } ' >foo
stty 'cat foo ' </dev/tty$i
sleep 2
# set raw mode with minimal input and output processing
stty -opost -icanon -isig -icrnl -echo -onlcr</dev/tty$i
rm foo
sync;sync
else
echo "Usage is fastport.sh < TTY number >"
fi

```

- Run the script for TTY number with the following command:
fastport.sh ttynumber

Tuning Name Resolution

TCP/IP attempts to obtain an Internet Protocol (IP) address from a host name in a process known as *name resolution*. The process of translating an Internet Protocol address into a host name is known as *reverse name resolution*. A *resolver routine* is used to resolve names. It queries DNS, NIS and finally the local **/etc/hosts** file to find the required information.

You can accelerate the process of name resolution by overwriting the default search order, if you know how you want names to be resolved. This is done through the use of the **/etc/netsvc.conf** file or the **NSORDER** environment variable. This feature is available in AIX 4.1 and later.

- If both the **/etc/netsvc.conf** file and the **NSORDER** are used, **NSORDER** overrides the **/etc/netsvc.conf** file. To specify host ordering with **/etc/netsvc.conf**, create the file and include the following line:

```
hosts=value,value,value
```

where *value* may be (lowercase only) bind, local, nis, bind4, bind6, local4, local6, nis4, or nis6 (for **/etc/hosts**). The order is specified on one line with values separated by commas. White spaces are permitted between the commas and the equal sign.

The values specified and their ordering is dependent on the network configuration. For example, if the local network is organized as a flat network, then only the **/etc/hosts** file is needed. The **/etc/netsvc.conf** file would contain the following line:

```
hosts=local
```

The **NSORDER** environment variable would be set as:

```
NSORDER=local
```

- If the local network is a domain network using a name server for name resolution and an **/etc/hosts** file for backup, specify both services. The **/etc/netsvc.conf** file would contain the following line:

```
hosts=bind,local
```

The **NSORDER** environment variable would be set as:

NSORDER=bind,local

The algorithm will attempt the first source in the list. The algorithm will then determine to try another specified service based on:

- Current service is not running; therefore, it is unavailable.
- Current service could not find the name and is not authoritative.

Improving telnetd/rlogind Performance

In AIX 4.2, the **rlogind** daemon was changed to move portions of its code into the pseudo tty driver (ptydd) in the kernel. This change eliminated context switches needed to transfer a single character from an application to a terminal. This feature is enabled by default and cannot be configured.

In AIX 4.3, this change was extended to the **telnetd** daemon. Data coming in goes directly from the socket layer to the pty device driver's slave side. This change eliminated the need for a context switch of the **telnetd** daemon to write incoming data to the PTS (pseudo-terminal slave).

This option is turned on by default in AIX 4.3.2 and later releases. Before AIX 4.3.2, you must add a **-a** flag to the **telnetd** daemon in **/etc/inetd.conf** and refresh the **inetd** daemon.

Expected performance improvements for the **rlogind** and **telnetd** daemons with this feature is about 50 percent.

Tuning the SP Network

This section provides information about network tunable parameters that need special attention in an SP environment. For a more detailed discussion on SP tuning, see *RS/6000 SP System Performance Tuning*.

SP Switch Statistics

Note: The commands in this section are SP-specific.

The estat Command

The unsupported and undocumented **estat** command can be helpful in determining SP Switch problems. The **entstat** command is located in the **/usr/lpp/ssp/css** directory and produces output similar to the **entstat** command. The output contains sections for transmit, receive, and general statistics.

The output that is helpful in determining SP Switch problems is Transmit Errors, Receive Errors, Packets Dropped, and No mbuf Errors. The second line in the output indicates how long the adapter has been online.

The vdidlxxx Commands

These unsupported and undocumented commands display the SP Switch pool usage since the SP Switch was last started. There are several commands called **vdidlxxx** (where **vdidl3** is for an MCA-based node, **vdidl3mx** for a 332 MHz node, and **vdidl3pci** for the S70 and S7A). These commands are found in the **/usr/lpp/ssp/css** directory on each node. For the SP Switch, only the send pool is used because microcode in the adapter manages the receive pool.

Following is an example for the **vdidl3** command:

```
# /usr/lpp/ssp/css/vdidl3 -i
send pool: size=524288 anchor@=0x50002c00 start@=0x50dc0000 tags@=0x50001d00
bkt  allocd    free  success    fail    split    comb    freed
 12      0        0         0         0         1         0         0
 13      0        0         0         0         0         0         0
 14      0        0         0         0         0         0         0
 15      0        0         0         0         0         0         0
 16      0         8         0         0         0         0         0
```

```

rsvd pool: size=262144 anchor@=0x50002000 start@=0x50e40000 tags@=0x50b84680
bkt  allocd      free  success      fail      split      comb      freed
 12      0         0       0         0         0         0         0
 13      0         0       0         0         0         0         0
 14      0         0       0         0         0         0         0
 15      0         0       0         0         0         0         0
 16      0         4       0         0         0         0         0
recv pool: size=524288 anchor@=0x50002e00 start@=0x50e80000 tags@=0x50001e00
bkt  allocd      free  success      fail      split      comb      freed
 12      0         0       0         0         0         0         0
 13      0         0       0         0         0         0         0
 14      0         0       0         0         0         0         0
 15      0         0       0         0         0         0         0
 16      0         0       0         0         0         0         0

```

Interpret the output carefully because some of the statistics have several meanings. For the SP Switch, only the send pool is used because the receive pool is managed by microcode in the adapter. Each column is described as follows:

bkt Lists the pool allocation in powers of 2 for the line it is on. The line starting with 12 means 2 to the 12th or 4 KB allocations, and the line starting with 16 means 2 to the 16th or 64 KB allocations.

allocd Lists the current allocations at the time the command was run, for each of the size allocations in the first column. This "snapshot" value fluctuates between successive executions of the command.

free Lists the number of buffers of each allocation that are allocated and unused at the time the command was run. In the above example, eight 64 K allocations are free for use. This instantaneous value can fluctuate between successive executions of the command.

success

This counter increments every time an allocation of the given size succeeded. This counter is cumulative, so it shows the number of successes since the adapter was last initialized.

fail

This counter is incremented every time an allocation is not available for the size requested. However, it is possible that the allocation is made by splitting up a larger allocation, or combining smaller ones into the size needed. A fail does *not* necessarily mean a packet was dropped. It is also possible that an allocation was split from a larger allocation without incurring a failed count. This counter is cumulative, so it shows the number of fails since the adapter was last initialized.

split

This counter indicates how many times the allocation size was extracted from the pool by carving the size needed from a larger allocation in the pool. This counter is cumulative, so it shows the number of splits since the adapter was last initialized.

comb

This field is currently not used.

freed

This field is currently not used.

SP System-Specific Tuning Recommendations

The following are specific details for setting the network tunables for the SP system.

arptab_bsiz

Number of ARP cache entries in each bucket (default = 7). See the following table for recommendations.

arptab_nb

Number of ARP cache buckets (default = 25). See the following table for recommendations.

CSS MTU size

The recommended MTU of a switch is 65520. However, under some circumstances (for example, when you want to avoid the Nagle algorithm causing very slow traffic), it may be necessary to reduce this value. You can reduce the MTU of a switch to 32678 with only a 2 to 10 percent loss in throughput. However, CPU utilization will be slightly higher due to the per-packet overhead.

To reduce the MTU of the switch, run the following:

ifconfig css0 mtu *new_size*

This command takes effect immediately and must be run as root user. Always use the same MTU across all nodes in an SP.

rfc1323

See rfc1323.

sb_max

See TCP Socket Buffer Tuning.

tcp_mssdfit

See When to Use the tcp_mssdfit Option of the no Command.

tcp_sendspace and tcp_recvspace

See TCP Socket Buffer Tuning. These parameters should never be higher than the major network adapter transmit queue limit. To calculate this limit, use:
*(major adapter queue size) * (major network adapter MTU)*

thewall

See Tuning Network Memory.

udp_sendspace and udp_recvspace

See UDP Socket Buffer Tuning.

By default, the maximum number of ARP entries allowed is 175 (25 * 7). This default value of 175 might not be large enough in SP environments with many nodes. An inadequate number of slots in the ARP cache will slow the performance of nodes in the system. Use the following table to estimate optimal values for the **arptab_nb** and **arptab_bsiz** variables.

Number of Nodes	arptab_nb	Number of Interfaces	arptab_bsiz
1 - 64	25	1 - 3	7
65 - 128	64	4	8
129 - 256	128	5	10
257 - 512	256	more...	2 times number of interfaces

In general, **arptab_nb** increases monotonically with the number of nodes and **arptab_bsiz** with the number of IP interfaces in an SP system.

These parameters must be placed in the first section of the **/etc/rc.net** file in front of the configuration methods.

Managing Tunable SP Parameters

The SP usually requires that tunable settings be changed from the default values in order to achieve optimal performance of the entire system. Placement of these tunable values is crucial. If they are not set in the correct places, subsequent rebooting of the nodes or other changes can cause them to change or be lost.

For all dynamically tunable values (those that take effect immediately), the setting for each node should be set in the **tuning.cust** file. This file is found in the **/ftpbboot** directory on each node. There is also a copy of the file in this same directory on the Control Work Station (CWS). Tunable parameters changed using the **no**, **nfso** or **vmtune** command can be included in this file. Even though the sample files do not include **nfso** and **vmtune** commands, the commands can be added.

A small number of tuning recommendations that are not dynamically tunable values need to be changed in the **rc.net** file. These tunable parameters are for ARP cache-tuning and setting the number of adapter types per interface. The following are the only tunable parameters that should be added to **rc.net**:

- **arptab_nb**
- **arptab_bsize**
- **arpqsize**
- **ifsize**

Using the sample **tuning.cust** settings selected as part of the installation is a sufficient starting point for the SP nodes in the environment type selected.

If the system has nodes that require different tuning settings, it is recommended that a copy of each setting be saved on the CWS. When nodes with specific tuning settings are installed, that version of **tuning.cust** must be moved into **/ftfboot** on the CWS.

Another option is to create one **tuning.cust** file that determines the node number, and based on that node number, sets the appropriate tuning values.

Initial Settings of SP Tunable Parameters

When a node is installed, migrated or customized, and that node's boot/install server does not have a **/ftfboot/tuning.cust** file, a default file with performance tuning variable settings in **/usr/lpp/ssp/install/tuning.default** is copied to **/ftfboot/tuning.cust** on that node. You can choose from one of the four sample tuning files, or you can create and customize your own. The existing files are located in the **/usr/lpp/ssp/install/config** directory and are as follows:

tuning.commercial

Contains initial performance tuning parameters for a typical commercial environment.

tuning.development

Contains initial performance tuning parameters for a typical interactive or development environment. These are the default tuning parameters.

tuning.scientific

Contains initial performance tuning parameters for a typical engineering/scientific environment.

tuning.server

Contains initial performance tuning parameters for a typical server environment.

The other option is to create and select your own alternate tuning file. While this may not be the initial choice, it certainly must be the choice at some point in time. On the CWS, create a **tuning.cust** file, or you can begin with one of the sample files. Edit the **tuning.cust** file and proceed to the installation of nodes. This **tuning.cust** file is then propagated to each node's **/ftfboot/tuning.cust** file from the boot/install server when the node is installed, migrated, or customized. The tuning file is maintained across reboots.

Tuning the SP Network for Specific Workloads

The following table provides a combined overview of tunable parameters for different environments. The settings given are only initial settings and are not guaranteed to be optimized for your environment. Examine your specific implementation and adjust your tuning settings accordingly.

Parameter	Commercial Environment	Server Environment	Scientific Environment	Development Environment
thewall	16384	65536	16384	16384
sb_max	1310720	1310720	1310720	1310720
subnetsarelocal	1	1	1	1

ipforwarding	1	1	1	1
tcp_sendspace	262144	65536	655360	65536
tcp_recvspace	262144	65536	655360	65536
udp_sendspace	65536	65536	65536	32768
udp_recvspace	655360	655360	655360	65536
rfc1323	1	1	1	1
tcp_mssdflt	1448	1448	Varies depending on other network types	1448
tcp_mtu_discover (AIX 4.2.1 and later)	1	1	1	1
udp_mtu_discover (AIX 4.2.1 and later)	1	1	1	1

Chapter 10. Monitoring and Tuning NFS Use

This chapter discusses Network File System (NFS) monitoring and tuning. It contains the following major sections:

- NFS Overview
- Analyzing NFS Performance
- Tuning for NFS Performance

NFS Overview

NFS allows programs on one system to access files on another system transparently by mounting the remote directory. Usually, when the server is booted, directories are made available by the **exportfs** command, and the daemons to handle remote access (**nfstd** daemons) are started. Similarly, the mounts of the remote directories and the initiation of the appropriate numbers of NFS block I/O daemons (**biod** daemon) to handle remote access are performed during client system boot.

Prior to AIX 4.2.1, **nfstd** and **biod** daemons were processes that required tuning the number of **nfstd** and **biod** daemons. Beginning with AIX 4.2.1, there is a single **nfstd** and **biod** daemon, each of which is multithreaded (multiple kernel threads within the process). Also, the number of threads is self-tuning in that it creates additional threads as needed.

The following figure illustrates the structure of the dialog between NFS clients and a server. When a thread in a client system attempts to read or write a file in an NFS-mounted directory, the request is redirected from the usual I/O mechanism to one of the client's **biod** daemon. The **biod** daemon sends the request to the appropriate server, where it is assigned to one of the server's NFS daemons (**nfstd** daemon). While that request is being processed, neither the **biod** nor the **nfstd** daemon involved do any other work.

Figure 26. NFS Client-Server Interaction. This illustration shows two clients and one server on a network that is laid out in a typical star topology. Client A is running thread m in which data is directed to one of its biod daemons. Client B is running thread n and directing data to its biod daemons. The respective daemons send the data across the network to server Z where it is assigned to one of the server's NFS (nfstd) daemons.

NFS uses Remote Procedure Calls (RPC) to communicate. RPCs are built on top of the External Data Representation (XDR) protocol which transforms data to a generic format before transmitting and allowing machines with different architectures to exchange information. The RPC library is a library of procedures that allows a local (client) process to direct a remote (server) process to execute a procedure call as if the

local (client) process had executed the procedure call in its own address space. Because the client and server are two separate processes, they no longer have to exist on the same physical system.

Figure 27. The Mount and NFS Process. This illustration is a three column table with Client Activity, Client, and Server as the three column headings. The first client activity is mount. An rpc call goes from the client to the server's portmapper mountd. The second client activity is open/close read/write. There is two-way interaction between the client's biod daemon and the server's nfsd daemon.

The **portmap** daemon, **portmapper**, is a network service daemon that provides clients with a standard way of looking up a port number associated with a specific program. When services on a server are requested, they register with **portmap** daemon as an available server. The **portmap** daemon then maintains a table of program-to-port pairs.

When the client initiates a request to the server, it first contacts the **portmap** daemon to see where the service resides. The **portmap** daemon listens on a well-known port so the client does not have to look for it. The **portmap** daemon responds to the client with the port of the service that the client is requesting. The client, upon receipt of the port number, is able to make all of its future requests directly to the application.

The **mountd** daemon is a server daemon that answers a client request to mount a server's exported file system or directory. The **mountd** daemon determines which file system is available by reading the **/etc/xtab** file. The mount process takes place as follows:

1. Client mount makes call to server's **portmap** daemon to find the port number assigned to the **mountd** daemon.
2. The **portmap** daemon passes the port number to the client.
3. The client **mount** command then contacts the server **mountd** daemon directly and passes the name of the desired directory.
4. The server **mountd** daemon checks **/etc/xtab** (built by the **exportfs -a** command, which reads **/etc/exports**) to verify availability and permissions on the requested directory.
5. If all is verified, the server **mountd** daemon gets a file handle (pointer to file system directory) for the exported directory and passes it back to the client's kernel.

The client only contacts the **portmap** daemon on its very first mount request after a system restart. Once the client knows the port number of the **mountd** daemon, the client goes directly to that port number for any subsequent mount request.

The **biod** daemon is the block input/output daemon and is required in order to perform read-ahead and write-behind requests, as well as directory reads. The **biod** daemon improves NFS performance by filling or emptying the buffer cache on behalf of the NFS clients. When a user on a client system wants to read or write to a file on a server, the **biod** daemon sends the requests to the server. The following NFS operations are sent directly to the server from the operating system's NFS client kernel extension and do not require the use of **biod** daemon:

- **getattr()**

- **setattr()**
- **lookup()**
- **readlink()**
- **create()**
- **remove()**
- **rename()**
- **link()**
- **symlink()**
- **mkdir()**
- **rmdir()**
- **readdir()**
- **readdirplus()**
- **fsstat()**

Prior to AIX 4.2.1, the default number of **bioid** daemons is six and can be increased or decreased as necessary for performance.

The **nfstd** daemon is the active agent providing NFS services from the NFS server. The receipt of any one NFS protocol request from a client requires the dedicated attention of an **nfstd** daemon until that request is satisfied and the results of the request processing are sent back to the client. Prior to AIX 4.2.1, the default number of **nfstd** daemons is eight and can be increased or decreased as necessary for performance.

NFS Version 3

NFS Version 3 was introduced in AIX 4.2.1. The operating system can support both NFS Version 2 and Version 3 on the same machine.

Prior to AIX 4.2.1, UDP was the exclusive transport protocol for NFS packets. TCP was added as an alternative protocol in AIX 4.2.1. UDP works efficiently over clean or efficient networks and responsive servers. For wide area networks or for busy networks or networks with slower servers, TCP may provide better performance because its inherent flow control can minimize retransmits on the network.

NFS Version 3 can enhance performance in many ways:

Write Throughput

Applications running on client systems may periodically write data to a file, changing the file's contents. The amount of time an application waits for its data to be written to stable storage on the server is a measurement of the *write throughput* of a global file system. Write throughput is therefore an important aspect of performance. All global file systems, including NFS, must ensure that data is safely written to the destination file while at the same time minimizing the impact of server latency on write throughput.

The NFS Version 3 protocol offers a better alternative to increasing write throughput by eliminating the synchronous write requirement of NFS Version 2 while retaining the benefits of close-to-open semantics. The NFS Version 3 client significantly reduces the number of write requests it makes to the server by collecting multiple requests and then writing the collective data through to the server's cache, but not necessarily to disk. Subsequently, NFS submits a commit request to the server that ensures that the server has written all the data to stable storage. This feature, referred to as *safe asynchronous writes*, can vastly reduce the number of disk I/O requests on the server, thus significantly improving write throughput.

The writes are considered "safe" because status information on the data is maintained, indicating whether it has been stored successfully. Therefore, if the server crashes before a commit operation, the client will know by looking at the status indication whether to resubmit a write request when the server comes back up.

Read Throughput

NFS sequential read throughput as measured at the client is enhanced via the VMM read-ahead and caching mechanisms. Read-ahead allows file data to be transferred to the client from the NFS server in anticipation of that data being requested by an NFS client application. By the time the request for data is issued by the application, it is possible that the data resides already in the client's memory, and thus the request can be satisfied immediately. VMM caching allows re-reads of file data to occur instantaneously, assuming that the data was not paged out of client memory which would necessitate retrieving the data again from the NFS server.

In addition, CacheFS, see Cache File System (CacheFS), may be used to further enhance read throughput in environments with memory-limited clients, very large files, and/or slow network segments by adding the potential to satisfy read requests from file data residing in a local disk cache on the client.

Reduced Requests for File Attributes

Because read data can sometimes reside in the cache for extended periods of time in anticipation of demand, clients must check to ensure their cached data remains valid if a change is made to the file by another application. Therefore, the NFS client periodically acquires the file's attributes, which includes the time the file was last modified. Using the modification time, a client can determine whether its cached data is still valid.

Keeping attribute requests to a minimum makes the client more efficient and minimizes server load, thus increasing scalability and performance. Therefore, NFS Version 3 was designed to return attributes for all operations. This increases the likelihood that the attributes in the cache are up to date and thus reduces the number of separate attribute requests.

Efficient Use of High Bandwidth Network Technology

NFS Version 2 has an 8 KB maximum buffer-size limitation, which restricts the amount of NFS data that can be transferred over the network at one time. In NFS Version 3, this limitation has been relaxed. The default read/write size is 32 KB for this operating system's NFS, enabling NFS to construct and transfer larger chunks of data. This feature allows NFS to more efficiently use high bandwidth network technologies such as FDDI, 100baseT and 1000baseT Ethernet, and the SP Switch, and contributes substantially to NFS performance gains in sequential read/write performance.

Reduced Directory "Lookup" Requests

A full directory listing (such as that produced by the **ls -l** command) requires that name and attribute information be acquired from the server for all entries in the directory listing. NFS Version 2 clients query the server separately for the file and directory names list and attribute information for all directory entries in a lookup request. With NFS Version 3, names list and attribute information is returned at one time, relieving both client and server from performing multiple tasks. However, in some environments, the NFS Version 3 **readdirplus()** operation might cause slower performance.

Changes Since AIX 4.2.1

Other changes in AIX 4.2.1 (for both NFS Version 2 and Version 3) include changes to the **nfsd**, **biod**, and **rpc.lockd** daemons. Prior to AIX 4.2.1, **nfsd** and **biod** daemons were processes that required tuning the number of **nfsd** and **biod** daemons. Beginning with AIX 4.2.1, there is a single **nfsd** and **biod** daemon each of which is multithreaded (multiple kernel threads within the process). Also, the number of threads is self-tuning in that it creates additional threads as needed. You can, however, tune the maximum number of threads by using the **nfsd** command and you can tune the maximum number of **biod** threads per mount via the **biods** mount option.

The **rpc.lockd** daemon was also changed to be multithreaded, so that many lock requests can be handled simultaneously.

Changes in AIX 4.3

Prior to AIX 4.3, the default protocol was UDP for both NFS Version 2 and NFS Version 3. With AIX 4.3 and later, TCP is now the default protocol for NFS Version 3, and the client can select different transport protocols for each mount, using the **mount** command options. You can use a new mount option (**proto**) to select TCP or UDP. For example:

```
# mount -o proto=tcp
```

Analyzing NFS Performance

NFS gathers statistics on types of NFS operations performed, along with error information and performance indicators. You can use the following commands to identify network problems and observe the type of NFS operations taking place on your system.

The **nfsstat** Command

The **nfsstat** command displays statistical information about the NFS and the RPC interface to the kernel for clients and servers. This command could also be used to reinitialize the counters for these statistics (**nfsstat -z**). For performance issues, the RPC statistics (**-r** option) are the first place to look. The NFS statistics show you how the applications use NFS.

RPC Statistics

The **nfsstat** command displays statistical information about RPC calls, such as:

- Total number of RPC calls received or rejected
- Total number of RPC calls sent or rejected by a server
- Number of times no RPC packet was available when trying to receive
- Number of packets that were too short or had malformed headers
- Number of times a call had to be transmitted again
- Number of times a reply did not match the call
- Number of times a call timed out
- Number of times a call had to wait on a busy client handle
- Number of times authentication information had to be refreshed

Starting with AIX 4.2.1, NFS Version 3 information is included. The NFS part of the **nfsstat** command output is divided into Version 2 and Version 3 statistics of NFS. The RPC part is divided into Connection oriented (TCP) and Connectionless (UDP) statistics.

NFS Server Information

The NFS server displays the number of NFS calls received (**calls**) and rejected (**badcalls**) due to authentication, as well as the counts and percentages for the various kinds of calls made.

The following example shows the server part of the **nfsstat** command output specified by the **-s** option, as follows:

```
# nfsstat -s

Server rpc:
Connection oriented:
calls    badcalls  nullrecv badlen    xdrCALL  dupchecks dupreqs
15835    0         0         0         0         772      0
Connectionless:
calls    badcalls  nullrecv badlen    xdrCALL  dupchecks dupreqs
0        0         0         0         0         0        0

Server nfs:
calls    badcalls  public_v2 public_v3
15835    0         0         0
Version 2: (0 calls)
```

null	getattr	setattr	root	lookup	readlink	read
0 0%	0 0%	0 0%	0 0%	0 0%	0 0%	0 0%
wrcache	write	create	remove	rename	link	symlink
0 0%	0 0%	0 0%	0 0%	0 0%	0 0%	0 0%
mkdir	rmdir	readdir	statfs			
0 0%	0 0%	0 0%	0 0%			
Version 3: (15835 calls)						
null	getattr	setattr	lookup	access	readlink	read
7 0%	3033 19%	55 0%	1008 6%	1542 9%	20 0%	9000 56%

commit						
97 0%						

RPC output for server (**-s**) is as follows:

calls Total number of RPC calls received from clients

badcalls

Total number of calls rejected by the RPC layer

nullrecv

Number of times an RPC call was not available when it was thought to be received

badlen

Packets truncated or damaged (number of RPC calls with a length shorter than a minimum-sized RPC call)

xdrCALL

Number of RPC calls whose header could not be External Data Representation (XDR) decoded

dupchecks

Number of RPC calls that looked up in the duplicate request cache

dupreqs

Number of duplicate RPC calls found

The output also displays a count of the various kinds of calls and their respective percentages.

Duplicate checks are performed for operations that cannot be performed twice with the same result. The classic example is the **rm** command. The first **rm** command will succeed, but if the reply is lost, the client will retransmit it. We want duplicate requests like these to succeed, so the duplicate cache is consulted, and if it is a duplicate request, the same (successful) result is returned on the duplicate request as was generated on the initial request.

By looking at the percentage of calls for different types of operations (such as **getattr()**, **read()**, **write()**, or **readdir()**), you can decide what type of tuning to use. For example, if the percentage of **getattr()** calls is very high, then tuning attribute caches may be advantageous. If the percentage of **write()** calls is very high, then disk and LVM tuning is important. If the percentage of **read()** calls is very high, then using more RAM for caching files could improve performance.

NFS Client Information

The NFS client displays the number of calls sent and rejected, as well as the number of times a client handle was received (**clgets**) and a count of the various kinds of calls and their respective percentages.

The following example shows the **nfsstat** output specified for clients using the **-c** option, as follows:

```
# nfsstat -c
Client rpc:
Connection oriented
calls    badcalls  badxids  timeouts  newcreds  badverfs  timers
```

```

0          0          0          0          0          0          0
nomem    cantconn interrupts
0          0          0
Connectionless
calls    badcalls retrans  badxids  timeouts newcreds badverfs
6553      0          0          0          0          0          0
timers  nomem    cantsend
0          0          0

```

Client nfs:

```

calls      badcalls  clgets    cltoomany
6541      0          0          0
Version 2: (6541 calls)
null      getattr   setattr   root       lookup     readlink   read
0 0%      590 9%    414 6%    0 0%      2308 35%  0 0%      0 0%
wrcache   write     create     remove     rename     link       symlink
0 0%      2482 37%  276 4%    277 4%    147 2%    0 0%      0 0%
mkdir     rmdir     readdir   statfs
6 0%      6 0%      30 0%     5 0%
Version 3: (0 calls)
null      getattr   setattr   lookup     access     readlink   read
0 0%      0 0%      0 0%      0 0%      0 0%      0 0%      0 0%
write     create     mkdir     symlink    mknod     remove     rmdir
0 0%      0 0%      0 0%      0 0%      0 0%      0 0%      0 0%
rename    link       readdir   readdir+   fsstat     fsinfo     pathconf
0 0%      0 0%      0 0%      0 0%      0 0%      0 0%      0 0%
commit
0 0%

```

RPC output for the client (-c) is as follows:

calls Total number of RPC calls made to NFS.

badcalls

Total number of calls rejected by the RPC layer.

retrans

Number of times a call had to be retransmitted due to a timeout while waiting for a reply from the server. This is applicable only to RPC over connection-less transports.

badxid

Number of times a reply from a server was received that did not correspond to any outstanding call. This means the server is taking too long to reply.

timeouts

Number of times a call timed-out while waiting for a reply from the server.

newcreds

Number of times authentication information had to be refreshed.

badverfs

Number of times a call failed due to a bad verifier in the response.

timers Number of times the calculated timeout value was greater than or equal to the minimum specified timeout value for a call.

nomem

Number of times a call failed due to a failure to allocate memory.

cantconn

Number of times a call failed due to a failure to make a connection to the server.

interrupts

Number of times a call was interrupted by a signal before completing.

cantsend

Number of times a send failed due to a failure to make a connection to the client.

The output also displays a count of the various kinds of calls and their respective percentages.

For performance monitoring, the **nfsstat -c** command provides information on whether the network is dropping UDP packets. A network may drop a packet if it cannot handle it. Dropped packets can be the result of the response time of the network hardware or software or an overloaded CPU on the server. Dropped packets are not actually lost, because a replacement request is issued for them.

The retrans column in the RPC section displays the number of times requests were retransmitted due to a timeout in waiting for a response. This situation is related to dropped UDP packets. If the retrans number consistently exceeds five percent of the total calls in column one, it indicates a problem with the server keeping up with demand. Use the **vmstat**, **netpmon**, and **iostat** commands on the server machine to check the load.

A high badxid count implies that requests are reaching the various NFS servers, but the servers are too loaded to send replies before the client's RPC calls time out and are retransmitted. The badxid value is incremented each time a duplicate reply is received for a transmitted request (an RPC request retains its XID through all transmission cycles). Excessive retransmissions place an additional strain on the server, further degrading response time. If badxid and timeouts are greater than five percent of the total calls, increase the **timeo** parameter of the NFS-mount options by using the **smitty chnfsmnt** command. If badxid is 0, but retrans and timeouts are sizable, attempt to decrease the NFS buffer size (that is, the **rsize** and **wsize** options of the **mount** command).

If the server is CPU-bound, NFS and its daemons are affected. To improve the situation, the server must be tuned or upgraded, or the user can localize the application files. If the server is I/O-bound, the server file systems can be reorganized, or localized files can be used.

If the number of retransmits and timeouts are close to the same value, it is certain that packets are being dropped. Packets are rarely dropped on the client. Usually, packets are dropped on either the network or on the server. The server could drop packets if it overflows its interface driver's transmit queue or if the server's User Datagram Protocol (UDP) socket buffer was overflowed (**nfs_socketsize**). If there are no socket buffer overflows or 0errs on the server, and the client is getting many retransmits and timeouts, packets are possibly being dropped on the network. Problems could occur in media and network devices, such as routers, bridges, or concentrators. Network sniffers and other tools can be used to debug such problems. See Dropped Packets for further discussion.

In some instances, an application or user experiences poor performance, yet examination of the **nfsstat -c** output indicates no or very few timeouts and retransmits. This means that the client is receiving responses from the server as fast as it is asking for them. The first thing to check is that there is an appropriate number of **bioid** daemons running on the client machine. This can also be observed when an application is doing remote file locking. When remote file locks are set on a file served over NFS, the client goes into a fully synchronous mode of operation that will turn off all data and attribute caching for the file. The result is very slow performance and is, unfortunately, normal. Locking packets can be identified in **ipreport** output by looking for NLM requests.

nfsstat -m: Since AIX 4.2.1, the **nfsstat -m** command displays the server name and address, mount flags, current read and write sizes, retransmission count, and the timers used for dynamic retransmission for each NFS mount on the client, as follows:

```
# nfsstat -m
/SAVE from /SAVE:itsorus.austin.ibm.com
Flags:  vers=2,proto=udp,auth=unix,soft,intr,dynamic,rsize=8192,wsize=8192,retrans=5
Lookups:  srttp=27 (67ms), dev=17 (85ms), cur=11 (220ms)
Reads:    srttp=16 (40ms), dev=7 (35ms), cur=5 (100ms)
Writes:   srttp=42 (105ms), dev=14 (70ms), cur=12 (240ms)
All:      srttp=27 (67ms), dev=17 (85ms), cur=11 (220ms)
```

The numbers in parentheses in the example output are the actual times in milliseconds. The other values are unscaled values kept by the operating system kernel. You can ignore the unscaled values. Response times are shown for lookups, reads, writes, and a combination of all of these operations (A11). Other definitions used in this output are as follows:

srtt Smoothed round-trip time
dev Estimated deviation
cur Current backed-off timeout value

The netpmon Command

See The netpmon Command for a discussion of this command and its output.

The nfso Command

The **nfso** command can be used to configure NFS attributes. It sets or displays network options in the currently running kernel. Therefore, the command must run after each system startup or network configuration.

Note: The **nfso** command performs no range-checking. If it is used incorrectly, the **nfso** command can make your system inoperable.

The **nfso** parameters and their values can be displayed by using the **nfso -a** command, as follows:

```
# nfso -a
portcheck= 0
udpchecksum= 1
nfs_socketsize= 60000
nfs_tcp_socketsize= 60000
nfs_setattr_error= 0
nfs_gather_threshold= 4096
nfs_repeat_messages= 0
nfs_udp_duplicate_cache_size= 0
nfs_tcp_duplicate_cache_size= 0
nfs_server_base_priority= 0
nfs_dynamic_retrans= 1
nfs_iopace_pages= 0
nfs_max_connections= 0
nfs_max_threads= 128
nfs_use_reserved_ports= 0
nfs_device_specific_bufs= 1
nfs_server_clread= 1
nfs_rfc1323= 0
nfs_max_write_size= 0
nfs_max_read_size= 0
nfs_allow_all_signals= 0
```

For a description of these attributes, see Network Tunable Parameters. Most NFS attributes are run-time attributes that can be changed at any time. Load time attributes, such as **nfs_socketsize**, need NFS to be stopped first and restarted afterwards.

To display or change a specific parameter, use the **nfso -o** command, as follows:

```
# nfso -o portcheck
portcheck= 0
# nfso -o portcheck=1
```

The parameters can be reset to their default value by using the **-d** option, as follows:

```
# nfso -d portcheck
# nfso -o portcheck
portcheck= 0
```

NFS References

Following is a summary of NFS-related files, commands, daemons, and subroutines. See the *AIX 5L Version 5.1 System Management Guide: Communications and Networks* and the *AIX 5L Version 5.1 Commands Reference* for details.

List of Network File System (NFS) Files

Following is a list of NFS files containing configuration information:

bootparams

Lists clients that diskless clients can use for booting

exports

Lists the directories that can be exported to NFS clients

networks

Contains information about networks on the Internet network

pcnfsd.conf

Provides configuration options for the **rpc.pcnfsd** daemon

rpc

Contains database information for Remote Procedure Call (RPC) programs

xtab

Lists directories that are currently exported

/etc/filesystems

Lists all the file systems that are attempted to be mounted at system restart

List of NFS Commands

Following is a list of NFS commands:

chnfs Starts a specified number of **biod** and **nfsd** daemons

mknfs Configures the system to run NFS and starts NFS daemons

nfso Configures NFS network options

automount

Mounts an NFS file system automatically

chnfsexp

Changes the attributes of an NFS-exported directory

chnfsmnt

Changes the attributes of an NFS-mounted directory

exportfs

Exports and unexports directories to NFS clients

lsnfsexp

Displays the characteristics of directories that are exported with NFS

lsnfsmnt

Displays the characteristics of mounted NFS systems

mknfsexp

Exports a directory using NFS

mknfsmnt

Mounts a directory using NFS

rmnfs Stops the NFS daemons

rmnfsexp

Removes NFS-exported directories from a server's list of exports

rmnfsmnt

Removes NFS-mounted file systems from a client's list of mounts

List of NFS Daemons

Following is a list of NFS locking daemons:

lockd Processes lock requests through the RPC package

statd Provides crash-and-recovery functions for the locking services on NFS

Following is a list of network service daemons and utilities:

biod Sends the client's read and write requests to the server

mountd

Answers requests from clients for file system mounts

nfsd Starts the daemons that handle a client's request for file system operations

pcnfsd

Handles service requests from PC-NFS clients

nfsstat

Displays information about a machine's ability to receive calls

on Executes commands on remote machines

portmap

Maps RPC program numbers to Internet port numbers

rexid Accepts request to run programs from remote machines

rpcgen

Generates C code to implement an RPC protocol

rpcinfo

Reports the status of RPC servers

rstatd Returns performance statistics obtained from the kernel

rup Shows the status of a remote host on the local network

rusers

Reports a list of users logged on to the remote machines

rusersd

Responds to queries from the **rusers** command

rwall Sends messages to all users on the network

rwalld Handles requests from the **rwall** command

showmount

Displays a list of all clients that have mounted remote file systems

spray Sends a specified number of packets to a host

sprayd

Receives packets sent by the **spray** command

Following is a list of secure networking daemons and utilities:

chkey Changes the user's encryption key

keyenvoy

Provides an intermediary between user processes and the key server

keylogin

Decrypts and stores the user's secret key

keyserv

Stores public and private keys

mkkeyserv

Starts the **keyserv** daemon and uncomments the appropriate entries in the **/etc/rc.nfs** file

newkey

Creates a new key in the public key file

rmkeyserv

Stops the **keyserv** daemon and comments the entry for the **keyserv** daemon in the **/etc/rc.nfs** file

ypupdated

Updates information in Network Information Service (NIS) maps

Following is a diskless client support configuration file:

bootparamd

Provides information necessary for booting to diskless clients

Following is a list of NFS subroutines:

cbc_crypt(), des_setparity(), or ecb_crypt()

Implements Data Encryption Standard (DES) routines.

Tuning for NFS Performance

In an NFS network, the server is the primary target for tuning, but a few things can be tuned on the client as well.

How Many **biod** and **nfsd** Daemons Are Needed?

Because **biod** and **nfsd** daemons handle one request at a time, and because NFS response time is often the largest component of overall response time, it is undesirable to have threads blocked for lack of a **biod** or **nfsd** daemon.

Note: Starting with AIX 4.2.1, there is a single **nfsd** daemon and a single **biod** daemon, each of which is multithreaded (multiple kernel threads within the process). Also, the number of threads is self-tuning in that it creates additional threads as needed. You can, however, tune the maximum number of **nfsd** threads by using the **nfs_max_threads** parameter of the **nfsd** command. You can also tune the maximum number of **biod** threads per mount via the **biod** mount option.

The general considerations for configuring NFS daemons are as follows:

- Increasing the number of daemons cannot compensate for inadequate client or server processor power or memory, or inadequate server disk bandwidth. Before changing the number of daemons, you should check server and client resource-utilization levels with the **iostat** and **vmstat** commands.
- If the CPU or disk subsystem is already at near-saturation level, an increase in the number of daemons will not yield better performance.
- NFS daemons are comparatively inexpensive. The **biod** or **nfsd** daemon costs a few pages in memory (some of them pinned). Of course, the unpinned pages are only in real memory if the **nfsd** or **biod** daemon has been active recently. Further, idle **nfsd** or **biod** daemons do not consume CPU time.
- All NFS requests go through an **nfsd** daemon; only reads and writes go through a **biod** daemon.

Choosing Initial Numbers of **nfsd** and **biod** Daemons

Determining the best numbers of **nfsd** and **biod** daemons is an iterative process. Guidelines can give you no more than a reasonable starting point.

The defaults are a good starting point for small systems, but should probably be increased for client systems with more than two users or servers with more than two clients. A few guidelines are as follows:

- In each client, estimate the maximum number of files that will be written simultaneously. Configure at least two **biod** daemons per file. If the files are large (more than 32 KB), you may want to start with four **biod** daemons per file to support read-ahead or write-behind activity. It is common for up to five **biod** daemons to be busy writing to a single large file.
- In each server, start by configuring as many **nfsd** daemons as the sum of the numbers of **biod** daemons that you have configured on the clients to handle files from that server. Add 20 percent to allow for non-read/write NFS requests.
- If you have fast client workstations connected to a slower server, you may have to constrain the rate at which the clients generate NFS requests. The best solution is to reduce the number of **biod** daemons on the clients, with due attention to the relative importance of each client's workload and response time.

Tuning the Numbers of **nfsd** and **biod** daemons

After you have arrived at an initial number of **biod** and **nfsd** daemons, or have changed one or the other, do the following:

- First, recheck the affected systems for CPU or I/O saturation with the **vmstat** and **iostat** commands. If the server is now saturated, you must reduce its load or increase its power, or both.
- Use the command **netstat -s** to determine if any system is experiencing UDP socket buffer overflows. If so, use the command **no -a** to verify that the recommendations in Tuning Other Layers to Improve NFS Performance have been implemented. If so, and the system is not saturated, increase the number of **biod** or **nfsd** daemons.
- Examine the `nullrecv` column in the **nfsstat -s** output. If the number starts to grow, it may mean there are too many **nfsd** daemons. However, this is less likely on this operating system's NFS servers than it is on other platforms. The reason for that is that all **nfsd** daemons are not awakened at the same time when an NFS request comes into the server. Instead, the first **nfsd** daemon wakes up, and if there is more work to do, this daemon wakes up the second **nfsd** daemon, and so on.

To change the numbers of **nfsd** and **biod** daemons, use the **chnfs** command.

To change the number of **nfsd** daemons on a server to 10, both immediately and at each subsequent system boot, use the following:

```
# chnfs -n 10
```

To change the number of **biod** daemons on a client to 8 temporarily, with no permanent change (that is, the change happens now but is lost at the next system boot), use the following:

```
# chnfs -N -b 8
```

To change both the number of **biod** daemons and the number of **nfsd** daemons on a system to 9, with the change delayed until the next system boot, run the following command:

```
# chnfs -I -b 9 -n 9
```

Increasing the number of **biod** daemons on the client worsens server performance because it allows the client to send more request at once, further loading the network and the server. In extreme cases of a client overrunning the server, it may be necessary to reduce the client to one **biod** daemon, as follows:

```
# stopsrc -s biod
```

This leaves the client with the kernel process **biod** still running.

Performance Implications of Hard or Soft NFS Mounts

One of the choices you make when configuring NFS-mounted directories is whether the mounts will be hard (**-o hard**) or soft (**-o soft**). When, after a successful mount, an access to a soft-mounted directory

encounters an error (typically, a timeout), the error is immediately reported to the program that requested the remote access. When an access to a hard-mounted directory encounters an error, NFS retries the operation.

A persistent error accessing a hard-mounted directory can escalate into a perceived performance problem because the default number of retries (1000) and the default timeout value (0.7 second), combined with an algorithm that increases the timeout value for successive retries, mean that NFS continues to try to complete the operation.

It is technically possible to reduce the number of retries, or increase the timeout value, or both, using options of the **mount** command. Unfortunately, changing these values sufficiently to remove the perceived performance problem might lead to unnecessary reported hard errors. Instead, use the **intr** option to mount the hard-mounted directories, which allows the user to interrupt from the keyboard a process that is in a retry loop.

Although soft-mounting the directories causes the error to be detected sooner, it runs a serious risk of data corruption. In general, read/write directories should be hard-mounted.

Other mount Options That Affect Performance

The **mount** command provides some NFS-tuning options that are often ignored or used incorrectly because of a lack of understanding of their use.

Before you start adjusting mount options, make certain that you know what you are trying to achieve with respect to packet delivery and packet turnaround on the server or network. You would use most of the NFS-specific mount options if your goal is to decrease the load on the NFS server, or to work around network problems.

The NFS performance-specific mount options are all specified as a list entry on the **-o** option for the **mount** command. Separate the options for the **-o** option on the command line only by a comma, not by a comma and a space.

The **rsize** and **wsize** Options

The most useful options are those for changing the read and write size values. These options define the maximum sizes of each RPC for read and write. Often, the **rsize** and **wsize** options of the **mount** command are decreased to decrease the read/write packet that is sent to the server. There can be two reasons why you might want to do this:

1. The server may not be capable of handling the data volume and speeds inherent in transferring the read/write packets (8 KB for NFS Version 2 and 32 KB for NFS Version 3). This might be the case if a NFS client is using a PC as an NFS server. The PC will likely have limited memory available for buffering large packets.
2. If a read/write size is decreased, there may be a subsequent reduction in the number of IP fragments generated by the call. If you are dealing with a faulty network, the chances of a call/reply pair completing with a two-packet exchange are greater than if there must be seven packets successfully exchanged. Likewise, if you are sending NFS packets across multiple networks with different performance characteristics, the packet fragments may not all arrive before the timeout value for IP fragments.

Reducing the **rsize** and **wsize** may improve the NFS performance in a congested network by sending shorter package trains for each NFS request. But a side effect is that more packets are needed to send data across the network, increasing total network traffic, as well as CPU utilization on both the server and client.

If your NFS file system is mounted across a high-speed network, such as the SP Switch, then larger read and write packet sizes would enhance NFS file system performance. With NFS Version 3, **rsize** and **wsiz**e can be set as high as 65536. The default is 32768. With NFS Version 2, the largest that **rsize** and **wsiz**e can be is 8192, which is also the default.

Disabling Unused NFS ACL Support

If your workload does not use the NFS access control list (ACL) support on a mounted file system, you can reduce the workload on both client and server to some extent by specifying the **noacl** option. This can be done as follows:

```
options=noacl
```

Set this option as part of the client's **/etc/filesystems** stanza for that file system.

Tune Retransmissions

Another **mount** command option to look at is **retrans**, which sets the number of NFS transmissions (the default is 3).

Tuning to Avoid Retransmits

Related to the hard-versus-soft mount question is the question of the appropriate timeout duration for a given network configuration. If the server is heavily loaded, is separated from the client by one or more bridges or gateways, or is connected to the client by a WAN, the default timeout criterion may be unrealistic. If so, both server and client are burdened with unnecessary retransmits. For example, if the following command:

```
# nfsstat -c
```

reports a significant number (greater 5 percent of the total) of both **timeouts** and **badxids**, you could increase the **timeo** parameter with the following SMIT fast path:

```
# smitty chnfsmnt
```

Identify the directory you want to change, and enter a new value on the line **NFS TIMEOUT. In tenths of a second**.

The default time is 0.7 second (**timeo=7**), but this value is manipulated in the NFS kernel extension depending on the type of call. For read calls, for instance, the value is doubled to 1.4 seconds.

To achieve control over the **timeo** value for operating system version 4 clients, you must set the **nfs_dynamic_retrans** option of the **nfs** command to 0. There are two directions in which you can change the **timeo** value, and in any given case, there is only one right way to change it. The correct way, making the timeouts longer or shorter, depends on why the packets are not arriving in the allotted time.

If the packet is only late and does finally arrive, then you may want to make the **timeo** variable longer to give the reply a chance to return before the request is retransmitted.

However, if the packet has been dropped and will never arrive at the client, then any time spent waiting for the reply is wasted time, and you want to make the **timeo** shorter.

One way to estimate which option to take is to look at a client's **nfsstat -cr** output and see if the client is reporting lots of **badxid** counts. A **badxid** value means that an RPC client received an RPC call reply that was for a different call than the one it was expecting. Generally, this means that the client received a duplicate reply for a previously retransmitted call. Packets are thus arriving late and the **timeo** should be lengthened.

Also, if you have a network analyzer available, you can apply it to determine which of the two situations is occurring. Lacking that, you can try setting the **timeo** option higher and lower and see what gives better

overall performance. In some cases, there is no consistent behavior. Your best option then is to track down the actual cause of the packet delays/drops and fix the real problem; that is, server or network/network device.

For LAN-to-LAN traffic through a bridge, try 50 (tenths of seconds). For WAN connections, try 200. Check the NFS statistics again after waiting at least one day. If the statistics still indicate excessive retransmits, increase **timeo** by 50 percent and try again. You will also want to examine the server workload and the loads on the intervening bridges and gateways to see if any element is being saturated by other traffic.

Dropped Packets

Given that dropped packets are detected on an NFS client, the real challenge is to find out where they are being lost. Packets can be dropped at the client, the server, and somewhere on the network.

Packets Dropped by the Client

Packets are rarely dropped by a client. Because each client RPC call is self-pacing, that is, each call must get a reply before going on, there is little opportunity for overrunning system resources. The most stressful operation is probably reading, where there is a potential for 1 MB+/sec of data flowing into the machine. While the data volume can be high, the actual number of simultaneous RPC calls is fairly small and each **biocd** daemon has its own space allocated for the reply. Thus, it is very unusual for a client to drop packets.

Packets are more commonly dropped either by the network or by the server.

Packets Dropped by the Server

Two situations exist where servers will drop packets under heavy loads:

1. Adapter Driver

When an NFS server is responding to a very large number of requests, the server will sometimes overrun the interface driver output queue. You can observe this by looking at the statistics that are reported by the **netstat -i** command. Examine the columns marked **0errs** and look for any counts. Each **0errs** is a dropped packet. This is easily tuned by increasing the problem device driver's transmit queue size. The idea behind configurable queues is that you do not want to make the transmit queue too long, because of latencies incurred in processing the queue. But because NFS maintains the same port and **XID** for the call, a second call can be satisfied by the response to the first call's reply. Additionally, queue-handling latencies are far less than UDP retransmit latencies incurred by NFS if the packet is dropped.

2. Socket Buffers

The second common place where a server will drop packets is the UDP socket buffer. Dropped packets here are counted by the UDP layer and the statistics can be seen by using the **netstat -p udp** command. Examine the statistics marked **UDP:** for the socket buffer overflows statistic.

NFS packets will usually be dropped at the socket buffer only when a server has a lot of NFS write traffic. The NFS server uses a UDP socket attached to NFS port 2049 and all incoming data is buffered on that UDP port. The default size of this buffer is 60,000 bytes. You can divide that number by the size of the default NFS write packet (8192) to find that it will take only eight simultaneous write packets to overflow that buffer. This overflow could occur with just two NFS clients (with the default configurations).

In this situation there is either high volume or high burst traffic on the socket.

- If there is high volume, a mixture of writes plus other possibly non-write NFS traffic, there may not be enough **nfsd** daemons to take the data off the socket fast enough to keep up with the volume. Recall that it takes a dedicated **nfsd** daemon to service each NFS call of any type.
- In the high burst case, there may be enough **nfsd** daemons, but the speed at which packets arrive on the socket is such that they cannot wake up fast enough to keep it from overflowing.

Each of the two situations is handled differently.

- In the case of high volume, it may be sufficient to just increase the number of **nfsd** daemons running on the system. Because there is no significant penalty for running with more **nfsd** daemons on a machine, try this solution first. Also, see *How Many biod and nfsd Daemons Are Needed?*.
- In the case of high burst traffic, the only solution is to enlarge the socket, in the hope that some reasonable size will be sufficiently large enough to give the **nfsd** daemons time to catch up with the burst. Memory dedicated to this socket will not be available for any other use, so it must be noted that a tuning objective of total elimination of socket buffer overflows by making the socket larger may result in this memory being underutilized for the vast majority of the time. A cautious administrator will watch the socket buffer overflow statistic, correlate it with performance problems, and determine how large to make the socket buffer. See *Increasing NFS Socket Buffer Size* for details on how to manipulate the NFS socket buffer.

You might see cases where the server has been tuned and no dropped packets are arriving for either the socket buffer or the driver `0errs`, but clients are still experiencing timeouts and retransmits. Again, this is a two-case scenario. If the server is heavily loaded, it may be that the server is just overloaded and the backlog of work for **nfsd** daemons on the server is resulting in response times beyond the default timeout set on the client. See *NFS Tuning Checklist* for hints on how to determine if this is the problem. The other possibility, and the most likely problem if the server is known to be otherwise idle, is that packets are being dropped on the network.

Dropped Packets On the Network

If there are no socket buffer overflows or `0errs` on the server, the client is getting lots of timeouts and retransmits and the server is known to be idle, then packets are most likely being dropped on the network. What is meant by when network is mentioned? It means a large variety of things including media and network devices such as routers, bridges, concentrators, and the whole range of things that can implement a transport for packets between the client and server.

Anytime a server is not overloaded and is not dropping packets, but NFS performance is bad, assume that packets are being dropped on the network. Much effort can be expended proving this and finding exactly how the network is dropping the packets. The easiest way of determining the problem depends mostly on the physical proximity involved and resources available.

Sometimes the server and client are in close enough proximity to be direct-connected, bypassing the larger network segments that may be causing problems. Obviously, if this is done and the problem is resolved, then the machines themselves can be eliminated as the problem. More often, however, it is not possible to wire up a direct connection, and the problem must be tracked down in place.

Tuning the NFS File-Attribute Cache

NFS maintains a cache on each client system of the attributes of recently accessed directories and files. Five parameters that can be set in the `/etc/filesystems` file control how long a given entry is kept in the cache. They are as follows:

actimeo

Absolute time for which file and directory entries are kept in the file-attribute cache after an update. If specified, this value overrides the following ***min** and ***max** values, effectively setting them all to the **actimeo** value.

acregmin

Minimum time after an update that file entries will be retained. The default is 3 seconds.

acregmax

Maximum time after an update that file entries will be retained. The default is 60 seconds.

acdirmin

Minimum time after an update that directory entries will be retained. The default is 30 seconds.

acdirmax

Maximum time after an update that directory entries will be retained. The default is 60 seconds.

Each time the file or directory is updated, its removal is postponed for at least **acregmin** or **acdirmin** seconds. If this is the second or subsequent update, the entry is kept at least as long as the interval between the last two updates, but not more than **acregmax** or **acdirmax** seconds.

Tuning for Maximum Caching of NFS Data

NFS does not have a data-caching function, but the Virtual Memory Manager (VMM) caches pages of NFS data just as it caches pages of disk data. If a system is essentially a dedicated NFS server, it may be appropriate to permit the VMM to use as much memory as necessary for data caching. This is accomplished by setting the **maxperm** parameter, which controls the maximum percentage of memory occupied by file pages, to 100 percent; for example:

```
# vmtune -P 100
```

The same technique could be used on NFS clients, but would only be appropriate if the clients were running workloads that had very little need for working-segment pages.

Cache File System (CacheFS)

The Cache File System can be used to enhance performance of remote file systems or slow devices such as CD-ROM. When a file system is cached, the data read from the remote file system or CD-ROM is stored in a cache on the local system, thereby avoiding the use of the network and NFS server when the same data is accessed for the second time. CacheFS is designed as a layered file system; this means that CacheFS provides the ability to cache one file system (the NFS file system, also called the back-file system) on another (your local file system, also called the front-file system), as shown in the following figure:

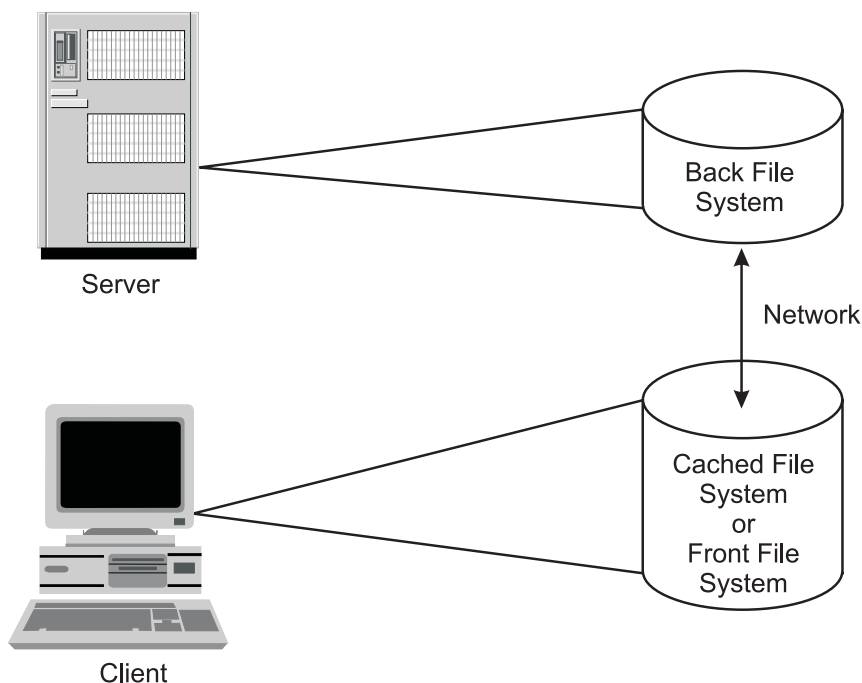

Figure 28. Cache File System (CacheFS). This illustration shows a client machine and a server that are connected by a network. The storage media on the server contains the back file system. The storage media on the client contains the cached file system or the front file system.

Note that in AIX 4.3, only NFS Version 2 and NFS Version 3 are supported as back-file systems, and JFS is the only supported front-file system.

CacheFS works as follows:

1. After creating a CacheFS file system on a client system, the system administrator specifies which file systems are to be mounted in the cache.
2. When a user on the client attempts to access files that are part of the back file system, those files are placed in the cache. The cache does not get filled until a user requests access to a file or files. Therefore, the initial request to access a file will be at typical NFS speeds, but subsequent accesses to the same file will be at local JFS speeds.
3. To ensure that the cached directories and files are kept up to date, CacheFS periodically checks the consistency of files stored in the cache. It does so by comparing the current modification time to the previous modification time.
4. If the modification times are different, all data and attributes for the directory or file are purged from the cache, and new data and attributes are retrieved from the back file system.

An example where CacheFS would be suitable is in a CAD environment where master-copies of drawing components can be held on the server and cached-copies on the client workstation when in use.

CacheFS does not allow reads and writes on files that are 2 GB or larger in size.

CacheFS Benefits

Because NFS data is cached on the local disk once it is read from the server, read requests to the NFS file system can be satisfied much faster than if the data had to be retrieved over the net again. Depending on the memory size and usage of the client, a small amount of data might be held and retrieved from memory, so that the benefits of cached data on the disk applies to a large amount of data that cannot be kept in memory. An additional benefit is that data on the disk cache will be held at system shutdown, whereas data cached in memory will have to be retrieved from the server again after the reboot.

Other potential NFS bottlenecks are a slow or busy network and a weak performing server with too many NFS clients to serve. Therefore, access from the client system to the server is likely to be slow. CacheFS will not prevent you from having to do the first read over the network and to access the server, but you can avoid reads over the network for further requests for the same data.

If more read requests can be satisfied from the client's local disk, the amount of NFS accesses to the server will decrease. This means that more clients can be served by the server; thus, the client per server ratio will increase.

Fewer read requests over the network will decrease your network load and, therefore, allow you to get some relief on very busy networks or space for other data transfers.

Not every application will benefit from CacheFS. Because CacheFS will only speed up read performance, mainly applications that have huge read requests for the same data over and over again will benefit from CacheFS. Large CAD applications will certainly benefit from CacheFS, because of the often very large models that they have to load for their calculations.

Performance tests showed that sequential reads from the CacheFS file system are 2.4 times to 3.4 times faster than reads from the NFS server's memory or disk.

What CacheFS Does Not Do

CacheFS will not increase the write performance to NFS file systems. However, you have two write options to choose as parameters to the **-o** option of the **mount** command, when mounting a CacheFS. They will influence the subsequent read performance to the data. The write options are as follows:

write-around

The write-around mode (the default) handles writes the same way that NFS does; that is, writes are made to the back file system, and the affected file is purged from the cache. This means that write-around voids the cache and new data must be obtained back from the server after the write.

non-shared

You can use the non-shared mode when you are certain that no one else will be writing to the

cached file system. In this mode, all writes are made to both the front and the back file system, and the file remains in the cache. This means that future read accesses can be done to the cache, rather than going to the server.

Small reads might be kept in memory anyway (depending on your memory usage); so there is no benefit in also caching the data on the disk. Caching of random reads to different data blocks does not help, unless you will access the same data over and over again.

The initial read request still has to go to the server because only by the time a user attempts to access files that are part of the back file system will those files be placed in the cache. For the initial read request, you will see typical NFS speed. Only for subsequent accesses to the same data, you will see local JFS access performance.

The consistency of the cached data is only checked at intervals. Therefore, it is dangerous to cache data that is frequently changed. CacheFS should *only* be used for read-only or read-mostly data.

Write Performance over a cached NFS file system differs from NFS Version 2 to NFS Version 3.

Performance tests have shown that:

- Sequential writes to a new file over NFS Version 2 to a CacheFS mount point can be 25 percent slower than writes directly to the NFS Version 2 mount point.
- Sequential writes to a new file over NFS Version 3 to a CacheFS mount point can be 6 times slower than writes directly to the NFS Version 3 mount point.

Configuring CacheFS

CacheFS is not implemented by default or prompted at the time of the creation of an NFS file system.

Make sure to install fileset level 4.3.1.1 for enhanced CacheFS write performance over NFS in AIX 4.3.1.

The system administrator must specify explicitly which file systems are to be mounted in the cache as follows:

1. Create the local cache file system by using the **cfsadmin** command:

```
# cfsadmin -c -o parameters cache-directory
```

where *parameters* specify the resource parameters and *cache-directory* is the name of the directory where the cache should be created.

2. Mount the back file system onto the cache:

```
# mount -V cachefs -o backfstype=nfs,cachedir=/cache-directory remhost:/rem-directory local-mount-point
```

where *rem-directory* is the name of the remote host and file system where the data resides, and *local-mount-point* is the mount point on the client where the remote file system should be mounted.

3. Alternately, you could administer CacheFS using the SMIT command (use the **smitty cachefs** fast path).

Several parameters can be set at creation time, as follows:

maxblocks

Sets the maximum number of blocks that CacheFS is allowed to claim within the front file system.
Default = 90 percent.

minblocks

Sets the minimum number of blocks that CacheFS is allowed to claim within the front file system.
Default = 0 percent.

threshblocks

Sets the number of blocks that must be available in the JFS file system on the client side before CacheFS can claim more than the blocks specified by **minblocks**. Default = 85 percent.

maxfiles

Maximum number of files that CacheFS can use, expressed as a percentage of the total number of i-nodes in the front file system. Default = 90 percent.

minfiles

Minimum number of files that CacheFS is always allowed to use, expressed as a percentage of the total number of i-nodes in the front file system. Default = 0 percent.

maxfilesize

Largest file size, expressed in megabytes, that CacheFS is allowed to cache. Default = 3.

Tuning Other Layers to Improve NFS Performance

NFS uses UDP or TCP to perform its network I/O. Ensure that you have applied the tuning techniques described in Tuning TCP and UDP Performance and Tuning mbuf Pool Performance. In particular, you should:

- Ensure that the LAN adapter transmit and receive queues are set to the maximum (see Adapter Transmit and Receive Queue Tuning).
- Increase the maximum socket buffer size (**sb_max**) to at least 131072 bytes. If the MTU size is not 4096 bytes or larger, set **sb_max** to at least 262144. Also set the UDP socket buffer sizes (**udp_sendspace** and **udp_recvspace**) to 131072 bytes. If you are using TCP, set **tcp_sendspace** and **tcp_recvspace** to this value.
- If possible, increase the MTU size on the LAN. On a 16 Mb Token-Ring, for example, an increase in MTU size from the default 1492 bytes to 8500 bytes allows a complete 8 KB NFS read or write request to be transmitted without fragmentation. It also makes much more efficient use of mbuf space, reducing the probability of overruns.
- A tunable parameter called **nfs_tcp_socketsize** provides default window sizes for TCP ports used in NFS connections. There is only one connect per client/server pair no matter how many mounts there are. Do not set the **nfs_tcp_socketsize** value to less than 60,000. Large or busy servers should have larger values until TCP NFS traffic shows no packets dropped from the output of the **netstat -s -p tcp** command.
- The maximum number of TCP connections allowed into the server can be controlled by the new option **nfs_max_connections**. The default of 0 indicates that there is no limit. The client will close TCP connections that have been idle for approximately 5 minutes, and the connection is reestablished when use warrants it. The server will close connections that have been idle for approximately 6 minutes.
- The operating system provides an option to turn off the UDP checksum for NFS only. You can use the **nfs** command option, called **udpchecksum**. The default is 1 (checksum enabled). Slight performance gains can be realized by turning it off, at the expense of increased chance of data corruption.

Increasing NFS Socket Buffer Size

In the course of tuning UDP, you may find that the **netstat -s** command indicates a significant number of UDP socket buffer overflows. As with ordinary UDP tuning, increase the **sb_max** value. You also need to increase the value of **nfs_socketsize**, which specifies the size of the NFS socket buffer. Following is an example:

```
# no -o sb_max=131072
# nfs -o nfs_socketsize=130972
```

The previous example sequence sets **sb_max** to a value at least 100 bytes larger than the desired value of **nfs_socketsize** and sets **nfs_socketsize** to 130972.

Note: In AIX Version 4, the **socketsize** is set dynamically. Configurations using the **no** and **nfs** command must be repeated every time the machine is booted. Add them in the **/etc/rc.net** or **/etc/rc.nfs** file immediately before the **nfsd** daemons are started and after the **biod** daemons are started. The position is *crucial*.

NFS Server Disk Configuration

NFS servers that experience high levels of write activity can benefit from configuring the journal logical volume on a separate physical volume from the data volumes. See Disk Preinstallation Guidelines for further details.

It is often necessary to achieve high parallelism on data access. Concurrent access to a single file system on a server by multiple clients or multiple client processes can result in throughput being bottlenecked on the disk I/O for a particular device. You can use the **iotstat** command to evaluate disk loading.

For large NFS servers, the general strategy should be to divide evenly the disk I/O demand across as many disk and disk adapter devices as possible. This results in greater parallelism and the ability to run greater numbers of **nfsd** daemons. On a system where disk I/O has been well-distributed, it is possible to reach a point where CPU load becomes the limiting factor on the server's performance.

Misuses of NFS That Affect Performance

Many of the misuses of NFS occur because people do not realize that the files that they are accessing are at the other end of an expensive communication path. A few examples of this are as follows:

- An application running on one system doing random updates of an NFS-mounted inventory file, supporting a real-time retail cash register application.
- A development environment in which a source code directory on each system was NFS-mounted on all of the other systems in the environment, with developers logging onto arbitrary systems to do editing and compiles. This practically guaranteed that all of the compiles would be obtaining their source code from, and writing their output to, remote systems.
- Running the **ld** command on one system to transform **.o** files in an NFS-mounted directory into an **a.out** file in the same directory.
- Applications that issue writes that are not pagealigned (for example 10 KB). Writes less than 4 KB in size will always result in a pagein and in the case of NFS, this pagein goes over the network.

It can be argued that these are valid uses of the transparency provided by NFS. Perhaps this is so, but these uses do cost processor time and LAN bandwidth and degrade response time. When a system configuration involves NFS access as part of the standard pattern of operation, the configuration designers should be prepared to defend the consequent costs with offsetting technical or business advantages, such as:

- Placing all of the data or source code on a server, rather than on individual workstations, improves source-code control and simplifies centralized backups.
- A number of different systems access the same data, making a dedicated server more efficient than one or more systems combining client and server roles.

Another type of application that should not be run across NFS file systems is an application that does hundreds of **lockf()** or **flock()** calls per second. On an NFS file system, all the **lockf()** or **flock()** calls (and other file locking calls) must go through the **rpc.lockd** daemon. This can severely degrade system performance because the lock daemon may not be able to handle thousands of lock requests per second.

Regardless of the client and server performance capacity, all operations involving NFS file locking will probably seem unreasonably slow. There are several technical reasons for this, but they are all driven by the fact that if a file is being locked, special considerations must be taken to ensure that the file is synchronously handled on both the read and write sides. This means there can be no caching of any file data at the client, including file attributes. All file operations go to a fully synchronous mode with no caching. Suspect that an application is doing network file locking if it is operating over NFS and shows unusually poor performance compared to other applications on the same client/server pair.

NFS Tuning Checklist

Following is a checklist that you can follow when tuning NFS:

1. Check to see if you are overrunning the server.

The general method is to see if slowing down the client will increase the performance. The following methods can be tried independently:

- Try running with just one **bioid** daemon on the mount.

Try running with just one **bioid** daemon on the affected client. If performance increases, then something is being overrun either in the network or on the server. Run the **stopsrc -s bioid** command to stop all the SRC **bioid** daemons. It will leave one kernel process **bioid** with which you can still run. See if it runs faster with just the one **bioid** process. If it has no effect, restart the **bioid** daemons with the **startsrc -s bioid** command. If it runs faster, attempt to determine where the packets are being dropped when all daemons are running. Networks, network devices, slow server, overloaded server, or a poorly tuned server could all cause this problem.

- Try reducing the read/write sizes to see if things speed up.
- If you are using UDP, try using a TCP mount instead.

2. Check for 0errs.

This is probably the most common under-configuration error that affects NFS servers.

If there are any 0errs, increase the transmit queues for the network device. This can be done with the machine running, but the interface must be detached before it is changed (**rmdev -l**). You cannot shut down the interface on a diskless machine, and you may not be at liberty to shut down the interface if other work is going on. In this case, you can use the **chdev** command to put the changes in ODM so they will be activated on the next boot. Start by doubling the current value for the queue length, and repeat the process (adding an additional 30 each time) until no 0errs are reported. On SP2 systems where NFS is configured to run across the high-speed switch, 0errs may occur on the switch when there has been a switch fault and the switch was temporarily unavailable. An error is counted towards 0err for each attempt to send on the switch that fails. These errors cannot be eliminated.

3. Look for any Errors.

Any counts that are very large indicate problems.

4. Check for NFS UDP/TCP buffer overruns.

When using UDP, buffer overruns on the NFS server are another frequent under-configuration for NFS servers. TCP sockets can be similarly overrun on very busy machines. Tuning for both is similar, so this section discusses only UDP.

Run the **netstat -s** command and examine the UDP statistics for the socket buffer overflows statistic. If it is anything other than 0, you are probably overrunning the NFS UDP buffer. Be aware, however, that this is the UDP socket buffer drop count for the entire machine, and it may or may not be NFS packets that are being dropped. You can confirm that the counts are due to NFS by correlating between packet drop counts on the client using the **nfsstat -cr** command to socket buffer overruns on the server while executing an NFS write test.

Socket buffer overflows can happen on heavily stressed servers or on servers that are slow in relation to the client. Up to 10 socket buffer overflows are probably not a problem. Hundreds of overflows are. If this number continually goes up while you watch it, and NFS is having performance problems, NFS needs tuning.

Two factors can tune NFS socket buffer overruns. First try increasing the number of **nfsd** daemons that are being run on the server. If that does not solve the problem, you must adjust two kernel variables, **sb_max**(socket buffer max) and **nfs_socketsize** (the size of the NFS server socket buffer). Use the **no** command to increase **sb_max**. Use the **nfs** command to increase the **nfs_socketsize** variable.

The **sb_max** parameter must be set larger than **nfs_socketsize**. It is hard to suggest new values. The best values are the smallest ones that also make the **netstat** report 0 or just produce a few socket buffer overruns.

Remember, in AIX Version 4, the socket size is set dynamically. Configurations using the **no** and **nfso** command must be repeated every time the machine is booted. Add them in the **/etc/rc.nfs** file, right before the **nfsd** daemons are started and after the **biocd** daemons are started. The position is crucial.

5. Check for mbuf problems.

See if there are any requests for mbufs denied or delayed. If so, increase the number of mbufs available to the network. For more information about tuning to eliminate mbuf problems, see Tuning mbuf Pool Performance.

6. Check for very small interpacket delays.

There have been rare cases where this has caused problems with machines. If there is a router or other hardware between the server and client, you can check its documentation to see if the interpacket delays can be configured. If so, try increasing the delay.

7. Check for media mismatches.

When packets are traversing two media with widely different speeds, the router might drop packets when taking them off the high speed net and trying to get them out on the slower net. This has been seen particularly when a router was trying to take packets from a server on FDDI and send them to a client on Ethernet. It could not send out the packets fast enough on Ethernet to keep up with the FDDI. The only solution is to try to slow down the volume of client requests, use smaller read/write sizes, and limit the number of **biocd** daemons that can be used on a single file system.

8. Check for MTU mismatches.

Run the **netstat -i** command and check the MTU on the client and server. If they are different, try making them the same and see if the problem is eliminated. Also be aware that slow or wide area networks between the machines, routers, or bridges, may further fragment the packets to traverse these network segments. Attempt to determine the smallest MTU between source and destination, and change the **rsize/wsize** on the NFS mount to some number lower than that lowest-common-denominator MTU.

9. Check for routing problems.

Use the **traceroute** command to look for unexpected routing hops or delays.

10. Check for errlog entries.

Run the **errpt** command and look for reports of network device or network media problems. Also look for any disk errors that might be affecting NFS server performance on exported file systems.

Chapter 11. Monitoring and Tuning Java

This chapter provides insights and general guidelines for isolating bottlenecks and tuning performance in Java applications.

What is Java?

Java is an object-oriented programming language developed by Sun Microsystems, Inc.. It is modeled after C++, and was designed to be small, simple, and portable across platforms and operating systems at the source and at the binary level. Java programs (applets and applications) can therefore run on any machine that has installed the Java Virtual Machine (JVM).

Why Java?

Java is a key component of Network Computing Framework (NCF), IBM's software road map for e-business. Java has significant advantages over other languages and other environments that make it suitable for just about any programming task.

The advantages of Java are as follows:

- Java is platform-independent.

One of the most significant advantages of Java is its ability to move easily from one computer system to another. Crucial to any World Wide Web software is the ability to run the same program on many different systems, Java succeeds at this by being platform-independent at both the source and binary levels.

- Java is object-oriented.

Another advantage of Java is the ability to take advantage of the object-oriented methodology. This allows you to create modular programs and reusable code.

- Java is easy to learn.

Java was designed to be easy to use and is therefore easier to write, compile, debug, and learn.

- Java is the solution to e-business.

Because of Java's robustness, ease of use, cross-platform capabilities and security features, it has become a language of choice for providing worldwide Internet solutions.

Java Performance Guidelines

The following are basic Java performance issues:

- Use **StringBuffer** instead of string concatenations, when doing excessive string manipulations to avoid unnecessarily creating objects that eventually need to be garbage collected.
- Avoid excessive writing to the Java console to reduce the cost of string manipulations, text formatting, and output.
- Avoid the costs of object creation and manipulation by using primitive types for variables when necessary.
- Cache frequently used objects to reduce the amount of garbage collection needed, and avoid the need to repeatedly create the objects.
- Group native operations to reduce the number of Java Native Interface (JNI) calls when possible.
- Use synchronized methods only when necessary, to limit the multitasking in the JVM and operating system.
- Avoid invoking the garbage collector unless necessary. If you must invoke it, do so only during idle time or some noncritical phase.
- Use **int** instead of **long** whenever possible, because 32-bit operations are executed faster than 64-bit.

- Declare methods as final whenever possible. Final methods are handled better by the JVM.
- Use the key word **static final** when creating constants in order to reduce the number of times the variables need to be initialized.
- Avoid unnecessary "casts" and "instanceof" references because casting in Java is not done at compile time but at run time.
- Avoid the use of vectors whenever possible when an array will suffice.
- Add and delete items from the end of the vector for better performance.
- Compile Java files with the **-O** option.

Monitoring Java

There are several possible solutions for monitoring Java performance.

- If you have access to the Java source code, add the following line in order to get the time spent on a code block.

```
System.currentTimeMillis()
```

- The JVM also provides the following option, which allows you to view the time that the CPU spent in doing garbage collection.

```
java -verbosegc <your_program>
```

- Others tools for monitoring Java are as follows:

- tprof
- hprof
- trace
- IBM/Alphaworks: Jinsight

Tuning Java

Certain environment parameters and settings can be used to tune Java performance within the operating system. In addition, many of the techniques for tuning system components, such as CPU, memory, network, I/O, and so on, can serve to increase Java performance. To determine which may be beneficial to your situation, refer to the specific sections in this book.

Use the following environmental settings:

- AIXTHREAD_COND_DEBUG=OFF
- AIXTHREAD_MUTEX_DEBUG=OFF
- AIXTHREAD_RWLOCK_DEBUG=OFF
- AIXTHREAD_SCOPE=S
- MALLOCMULTIHEAP=1
- SPINLOOPTIME=500

Usually the first limit that is reached is the number of file descriptors a process may have. Independently of Java, it is recommended to set this number to at least 40000 with the following command:

```
# ulimit -n 40000
```

It is also recommended that you set the Transmit Queue Size to 2048 as described in Adapter Transmit and Receive Queue Tuning.

Because the JVM searches the directories in the order in which they appear in the **CLASSPATH** environment variable, reorder the **CLASSPATH** environment variable so that the most commonly used libraries appear before any others.

The most common performance bottleneck encountered in Java applications is Garbage Collection (GC). GC is a single-threaded process that reclaims memory locations that are no longer being used by any portion of the currently executing program. When GC runs, all other threads are stopped until it has completed.

To improve GC performance, do the following:

- Reduce the amount of object creations in your application by reusing existing objects whenever possible.
- Adjust your Java heap sizes by using the **-ms** and **-mx** options. For example:

```
# java -ms128M -mx128M your_program
```

To obtain the best possible Java performance and scalability, it is recommended that you use the latest version of the operating system and the latest available JVM and Just In Time (JIT) versions.

Chapter 12. Analyzing Performance with the Trace Facility

The operating system's trace facility is a powerful system-observation tool. The trace facility captures a sequential flow of time-stamped system events, providing a fine level of detail on system activity. Events are shown in time sequence and in the context of other events. Trace is a valuable tool for observing system and application execution. Unlike other tools that only provide CPU utilization or I/O wait time, trace expands that information to aid in understanding what events are happening, who is responsible, when the events are taking place, how they are affecting the system and why.

The operating system is instrumented to provide general visibility to system execution. Users can extend visibility into their applications by inserting additional events and providing formatting rules.

Care was taken in the design and implementation of this facility to make the collection of trace data efficient, so that system performance and flow would be minimally altered by activating trace. Because of this, the trace facility is extremely useful as a performance-analysis tool and as a problem-determination tool.

The following sections provide more information on the trace facility:

- Understanding the Trace Facility
- Example of Trace Facility Use
- Starting and Controlling Trace from the Command Line
- Starting and Controlling Trace from a Program
- Using the `trcrpt` Command to Format a Report
- Adding New Trace Events

Understanding the Trace Facility

The trace facility is more flexible than traditional system-monitor services that access and present statistics maintained by the system. It does not presuppose what statistics will be needed, instead, trace supplies a stream of events and allows the user to decide what information to extract. With traditional monitor services, data reduction (conversion of system events to statistics) is largely coupled to the system instrumentation. For example, many systems maintain the minimum, maximum, and average elapsed time observed for executions of task A and permit this information to be extracted.

The trace facility does not strongly couple data reduction to instrumentation, but provides a stream of trace event records (usually abbreviated to *events*). It is not necessary to decide in advance what statistics will be needed; data reduction is to a large degree separated from the instrumentation. The user may choose to determine the minimum, maximum, and average time for task A from the flow of events. But it is also possible to:

- Extract the average time for task A when called by process B
- Extract the average time for task A when conditions XYZ are met
- Calculate the standard deviation of run time for task A
- Decide that some other task, recognized by a stream of events, is more meaningful to summarize.

This flexibility is invaluable for diagnosing performance or functional problems.

In addition to providing detailed information about system activity, the trace facility allows application programs to be instrumented and their trace events collected in addition to system events. The trace file then contains a complete record of the application and system activity, in the correct sequence and with precise time stamps.

Implementation

A *trace hook* is a specific event that is to be monitored. A unique number is assigned to that event called a *hook ID*. The **trace** command monitors these hooks.

The **trace** command generates statistics on user processes and kernel subsystems. The binary information is written to two alternate buffers in memory. The **trace** process then transfers the information to the trace log file on disk. This file grows very rapidly. The **trace** program runs as a process which may be monitored by the **ps** command. The **trace** command acts as a daemon, similar to accounting.

The following figure illustrates the implementation of the trace facility.

Figure 29. Implementation of the Trace Facility. This illustration shows the trace process. In this process, the user process (kernel subsystems) sends trace hook calls to trace buffers labeled A and B. From the buffers, they pass through the trace driver and on to the trace log file of the user kernel.

Monitoring facilities use system resources. Ideally, the overhead should be low enough as to not significantly affect system execution. When the **trace** program is active, the CPU overhead is less than 2 percent. When the trace data fills the buffers and must be written to the log, additional CPU is required for file I/O. Usually this is less than 5 percent. Because the **trace** program claims and pins buffer space, if the environment is memory-constrained, this might be significant. Be aware that the trace log and report files can become very large.

Limiting the Amount of Trace Data Collected

The trace facility generates large volumes of data. This data cannot be captured for extended periods of time without overflowing the storage device. There are two ways to use the trace facility efficiently:

- The trace facility can be turned on and off in multiple ways to capture system activity. It is practical to capture in this way seconds to minutes of system activity for post processing. This is enough time to characterize major application transactions or interesting sections of a long task.
- The trace facility can be configured to direct the event stream to standard output. This allows a real-time process to connect to the event stream and provide data reduction as the events are recorded, thereby creating long-term monitoring capability. A logical extension for specialized instrumentation is to direct the data stream to an auxiliary device that can either store massive amounts of data or provide dynamic data reduction. This technique is used by the performance tools **tprof**, **pprof**, **netpmn**, and **filemon**.

Starting and Controlling Trace

The trace facility provides three distinct modes of use:

Subcommand Mode

Trace is started with a shell command (**trace**) and carries on a dialog with the user through subcommands. The workload being traced must be provided by other processes, because the original shell process is in use.

Command Mode

Trace is started with a shell command (**trace -a**) that includes a flag which specifies that the trace facility is to run asynchronously. The original shell process is free to run ordinary commands, interspersed with trace-control commands.

Application-Controlled Mode

Trace is started with the **trcstart()** subroutine and controlled by subroutine calls such as **trcon()** and **trcoff()** from an application program.

Formatting Trace Data

A general-purpose trace-report facility is provided by the **trcrpt** command. The report facility provides little data reduction, but converts the raw binary event stream to a readable ASCII listing. Data can be visually extracted by a reader, or tools can be developed to further reduce the data.

The report facility displays text and data for each event according to rules provided in the trace format file. The default trace format file is **/etc/trcfmt**, which contains a stanza for each event ID. The stanza for the event provides the report facility with formatting rules for that event. This technique allows users to add their own events to programs and insert corresponding event stanzas in the format file to specify how the new events should be formatted.

Viewing Trace Data

When trace data is formatted, all data for a given event is usually placed on a single line. Additional lines may contain explanatory information. Depending on the fields included, the formatted lines can easily exceed 80 characters. It is best to view the reports on an output device that supports 132 columns.

Example of Trace Facility Use

The following takes you through an example of a typical trace.

Note: This example is more meaningful if the input file is not already cached in system memory. Choose as the source file any file that is about 50 KB in size and has not been used recently.

Obtaining a Sample Trace File

Trace data accumulates rapidly. Bracket the data collection as closely around the area of interest as possible. One technique for doing this is to issue several commands on the same command line. For example:

```
# trace -a -k "20e,20f" -o trc_raw ; cp ../bin/track /tmp/junk ; trcstop
```

captures the execution of the **cp** command. We have used two features of the **trace** command. The **-k "20e,20f"** option suppresses the collection of events from the **lockl()** and **unlockl()** functions. These calls are numerous on uniprocessor systems, but not on SMP systems, and add volume to the report without giving us additional information. The **-o trc_raw** option causes the raw trace output file to be written in our local directory.

Formatting the Sample Trace

We use the following form of the **trcrpt** command for our report:

```
# trcrpt -0 "exec=on,pid=on" trc_raw > cp.rpt
```

This reports both the fully qualified name of the file that is run and the process ID that is assigned to it.

The report file shows us that there are numerous VMM page assign and delete events in the trace, like the following sequence:

```
1B1 ksh          8526          0.003109888      0.162816
      VMM page delete:      V.S=0000.150E ppage=1F7F
      working_storage delete_in_progress process_private computational

1B0 ksh          8526          0.003141376      0.031488
      VMM page assign:      V.S=0000.2F33 ppage=1F7F
      working_storage delete_in_progress process_private computational
```

We are not interested in this level of VMM activity detail at the moment, so we reformat the trace as follows:

```
# trcrpt -k "1b0,1b1" -o "exec=on,pid=on" trc_raw > cp.rpt2
```

The **-k "1b0,1b1"** option suppresses the unwanted VMM events in the formatted output. It saves us from having to retrace the workload to suppress unwanted events. We could have used the **-k** function of the **trcrpt** command instead of that of the **trace** command to suppress the **lockl()** and **unlockl()** events, if we had believed that we might need to look at the lock activity at some point. If we had been interested in only a small set of events, we could have specified **-d "hookid1,hookid2"** to produce a report with only those events. Because the hook ID is the leftmost column of the report, you can quickly compile a list of hooks to include or exclude. A comprehensive list of trace hook IDs is defined in the **/usr/include/sys/trchkid.h** file.

Reading a Trace Report

The header of the trace report tells you when and where the trace was taken, as well as the command that was used to produce it:

```
Thu Oct 28 13:34:05 1999
System: AIX texmex Node: 4
Machine: 000691854C00
Internet Protocol Address: 09359BBB 9.53.155.187
Buffering: Kernel Heap
```

```
trace -a -k 20e,20f -o trc_raw
```

The body of the report, if displayed in a small enough font, looks similar to the following:

ID	PROCESS NAME	PID	ELAPSED_SEC	DELTA_MSEC	APPL	SYSCALL	KERNEL	INTERRUPT
101	ksh	8526	0.005833472	0.107008		kfork	LR = D0040AF8	
101	ksh	7214	0.012820224	0.031744		execve	LR = 10015390	
134	cp	7214	0.014451456	0.030464		exec:	cmd=cp ../bin/track /tmp/junk pid=7214 tid=24713	

In **cp.rpt2** you can see the following information:

- The **fork()**, **exec()**, and page fault activities of the **cp** process.
- The opening of the input file for reading and the creation of the **/tmp/junk** file
- The successive **read()/write()** system calls to accomplish the copy.
- The process **cp** becoming blocked while waiting for I/O completion, and the **wait** process being dispatched.
- How logical-volume requests are translated to physical-volume requests.
- The files are mapped rather than buffered in traditional kernel buffers, and the read accesses cause page faults that must be resolved by the Virtual Memory Manager.
- The Virtual Memory Manager senses sequential access and begins to prefetch the file pages.
- The size of the prefetch becomes larger as sequential access continues.
- When possible, the disk device driver coalesces multiple file requests into one I/O request to the drive.

The trace output looks a little overwhelming at first. This is a good example to use as a learning aid. If you can discern the activities described, you are well on your way to being able to use the trace facility to diagnose system-performance problems.

Filtering of the Trace Report

The full detail of the trace data may not be required. You can choose specific events of interest to be shown. For example, it is sometimes useful to find the number of times a certain event occurred. To answer the question "How many opens occurred in the copy example?" first find the event ID for the **open()** system call. This can be done as follows:

```
# trcrpt -j | grep -i open
```

You should be able to see that event ID 15b is the OPEN SYSTEM CALL event. Now, process the data from the copy example as follows:

```
# trcrpt -d 15b -0 "exec=on" trc_raw
```

The report is written to standard output, and you can determine the number of **open()** subroutines that occurred. If you want to see only the **open()** subroutines that were performed by the **cp** process, run the report command again using the following:

```
# trcrpt -d 15b -p cp -0 "exec=on" trc_raw
```

Starting and Controlling Trace from the Command Line

The trace facility is configured and data collection optionally started by the **trace** command, the detailed syntax of which is described in the *AIX 5L Version 5.1 Commands Reference*.

After trace is configured by the **trace** command, there are controls to turn data collection on and off and to stop the trace facility (the **trcstop** subcommand deconfigures **trace** and unpins buffers). You can invoke the controls through: subcommands, commands, subroutines, and **ioctl()** calls. The subroutine and **ioctl()** interfaces are described in Starting and Controlling Trace from a Program.

Controlling Trace in Subcommand Mode

If the **trace** routine is configured without the **-a** option, it runs in subcommand mode. Instead of the normal shell prompt, a prompt of **"->"** displays. In this mode, the following subcommands are recognized:

trcon Starts or resumes collection of event data

trcoff Suspends collection of event data

q or **quit**

Stops collection of event data and terminates the **trace** routine

!command

Runs the specified shell command

?

Displays the available commands

For example:

```
# trace -f -m "Trace of events during mycmd"
-> !mycmd
-> q
#
```

Controlling Trace by Commands

If the **trace** routine is configured to run asynchronously (**trace -a**), trace can be controlled by the following commands:

trcon Starts or resumes collection of event data

trcoff Suspends collection of event data

trcstop

Stops collection of event data and terminates the **trace** routine

For example:

```
# trace -a -n -L 2000000 -T 1000000 -d -o trace.out
# trcon
# cp /a20kfile /b
# trcstop
```

By specifying the **-d** (defer tracing until the **trcon** subcommand is entered) option, you can limit how much tracing is done on the **trace** command itself. If the **-d** option is not specified, then tracing begins immediately and can log events for the **trace** command initializing its own memory buffers. Typically, we want to trace everything but the **trace** command itself.

By default, the kernel buffer size (**-T** option) can be at most one half of the log buffer size (**-L** option). If you use the **-f** flag, the buffer sizes can be the same.

The **-n** option is useful if there are kernel extension system calls that need to be traced.

Starting and Controlling Trace from a Program

The trace facility can be started from a program, through a subroutine call. The subroutine is **trcstart()** and is in the **librts.a** library. The syntax of the **trcstart()** subroutine is as follows:

```
int trcstart(char *args)
```

where *args* is the options list that you would have entered for the **trace** command. By default, the system trace (channel 0) is started. If you want to start a generic trace, include a **-g** option in the *args* string. On successful completion, the **trcstart()** subroutine returns the channel ID. For generic tracing, this channel ID can be used to record to the private generic channel.

When compiling a program using this subroutine, the link to the **librts.a** library must be specifically requested (use **-l rts** as a compile option).

Controlling Trace with Trace Subroutine Calls

The controls for the **trace** routine are available as subroutines from the **librts.a** library. The subroutines return zero on successful completion. The subroutines are:

int trcon()

Begins or resumes collection of trace data.

int trcoff()

Suspends collection of trace data.

int trcstop()

Stops collection of trace data and terminates the **trace** routine.

Controlling Trace with ioctl() Calls

Each of the above subroutines for controlling trace performs the following tasks:

- Opens the trace control device (**/dev/systctl**)
- Issues the appropriate **ioctl()** subroutine
- Closes the control device
- Returns to the calling program

To turn tracing on and off around individual sections of code, it may be more efficient for a program to issue the **ioctl()** controls directly. This method avoids the repetitive opening and closing of the trace control device. To use the **ioctl()** interface in a program, include **sys/trcctl.h** to define the **ioctl()** commands. The syntax of the **ioctl()** subroutine is as follows:

```
ioctl (fd, CMD, Channel)
```

where:

fd is the file descriptor returned from opening **/dev/systrctl**

CMD is one of: TRCON, TRCOFF, or TRCSTOP

Channel

is the trace channel (0 for system trace)

The following code example shows how to start a trace from a program and only trace around a specified section of code:

```
#include <fcntl.h>
#include <sys/trcctl.h>
extern int trcstart(char *arg);
char *ctl_dev = "/dev/systrctl";
int ctl_fd;
main()
{
    printf("configuring trace collection \n");
    if (trcstart("-ad")){
        perror("trcstart");
        exit(1);
    }

    printf("opening the trace device \n");
    if((ctl_fd =open (ctl_dev,0_RDWR))<0){
        perror("open ctl_dev");
        exit(1);
    }

    printf("turning data collection on \n");
    if(ioctl(ctl_fd,TRCON,0)){
        perror("TRCON");
        exit(1);
    }

    /* *** code here will be traced *** */
    printf("The code to print this line will be traced.");

    printf("turning data collection off\n");
    if (ioctl(ctl_fd,TRCOFF,0)){
        perror("TRCOFF");
        exit(1);
    }

    printf("stopping the trace daemon \n");
    if (trcstop(0)){
        perror("trcstop");
        exit(1);
    }

    exit(0);
}
```

Because no output file was specified in the parameter to the **trcstart()** subroutine, the output of the trace is in **/var/adm/ras/trcfile**, which is also the default input file of the **trcrpt** command.

Using the trcrpt Command to Format a Report

The trace report facility reads the trace log file, formats the trace entries, and writes a report. The **trcrpt** command displays text and data for each event according to rules provided in the trace format file (**/etc/trcfmt**). Stanzas in the format file provide formatting rules for events or hooks. Users adding hooks to programs can insert corresponding event stanzas in the format file to print their trace data (see Adding New Trace Events).

The **trcrpt** facility does not produce any summary reports, but you can use the **awk** command to create simple summaries through further processing of the **trcrpt** output.

The detailed syntax of the **trcrpt** command is described in the *AIX 5L Version 5.1 Commands Reference*.

Formatting a Report on the Same System

The **trcrpt** command formats reports of trace event data contained in the trace log file. You can specify the events to be included (or omitted) in the report, as well as determine the presentation of the output with this command.

You can use the System Management Interface Tool (SMIT) to run the **trcrpt** command by typing the SMIT fast path:

```
# smitty trcrpt
```

To create a trace report to the newfile file, type:

```
# trcrpt -o newfile
```

Formatting a Report on a Different System

It is often desirable to run the **trcrpt** command on another system than the system where the trace is collected. There may be various reasons for this, such as:

- The system being traced might not be available for you to run the **trcrpt** command, and the trace might be collected by the system administrator or someone at the remote site.
- The system being traced is too busy for you to run the **trcrpt** command.
- The system being traced does not have enough file system space left to accommodate a very large **trcrpt** file.

You can run the **trace** command on a system and run the **trcrpt** command on that trace file on a different system. In order for this to work correctly, the output of the **trcnm** command is needed from the system where the trace was run. Run the **trcnm** command and redirect the output into a file, as follows:

```
# trcnm > trace.nm
```

If you want to use the trace file for other performance tools such as **tprof**, **pprof**, **netpmon**, and **filemon**, run the **gennames** *Ggennames_File* command.

That file is then used with the **-n** flag of the **trcrpt** command, as follows:

```
# trcrpt -n trace.nm -o newfile
```

If **-n** is not specified, then the **trcrpt** command generates a symbol table from the system on which the **trcrpt** command is run.

Additionally, a copy of the **/etc/trcfmt** file from the system being traced might be beneficial because that system may have different or more trace format stanzas than the system where the **trcrpt** command is being run. The **trcrpt** command can use the **-t** flag to specify the trace format file (by default it uses the **/etc/trcfmt** file from the system where the **trcrpt** command is being run). For example:

```
# trcrpt -n trace.nm -t trcfmt_file -o newfile
```

Formatting a Report from trace -C Output

If trace was run with the **-C** flag, one or more trace output files are generated. For example, if the trace file name was specified as **trace.out** and **-C all** was specified on a 4-way SMP, then a **trace.out**, **trace.out-1**, **trace.out-2**, **trace.out-3**, and **trace.out-4** file was generated. When you run the **trcrpt** command, specify **trcrpt -C all** and **trace.out** as the file name, and all the files will be read, as follows:

```
# trcrpt -C all -r trace.out > trace.tr
```

This **trace.tr** file can then be used as input for other commands (it will include the trace data from each CPU). The reason for the **-C** flag on trace is so that the trace can keep up with each CPU's activities on those systems which have many CPUs (more than 12, for example). Another reason is that the buffer size for the trace buffers is per CPU when you use the **-C all** flag.

Adding New Trace Events

The operating system is shipped instrumented with key events. The user need only activate trace to capture the flow of events from the operating system. Application developers may want to instrument their application code during development for tuning purposes. This provides them with insight into how their applications are interacting with the system.

To add a trace event, you must design the trace records generated by your program in accordance with trace interface conventions. You then add trace-hook macros to the program at the appropriate locations. Traces can then be taken through any of the standard ways of invoking and controlling trace (commands, subcommands, or subroutine calls). To use the **trcrpt** program to format your traces, add stanzas describing each new trace record and its formatting requirements to the trace format file.

Possible Forms of a Trace Event Record

A trace event can take several forms. An event consists of a hook word, optional data words, and an optional time stamp, as shown in the following figure. A four-bit type is defined for each form that the event record can take. The type field is imposed by the recording routine so that the report facility can always skip from event to event when processing the data, even if the formatting rules in the trace format file are incorrect or missing for that event.

12-bit Hook ID	4-bit Type	16-bit Data Field	Hook Word (required)
		Data Word 1	D1 (optional)
		Data Word 2	D2 (optional)
		Data Word 3	D3 (optional)
		Data Word 4	D4 (optional)
		Data Word 5	D5 (optional)
		32-bit Time Stamp	T (optional)

Figure 30. Format of a Trace Event Record. This illustration is a table containing 7 rows. Cells in the first row are labeled 12-bit hook ID, 4-bit Type and 16-bit Data Field. The next 6 rows are simply labeled Data Word 1 through Data Word 5, and the last row is labeled 32-bit Time Stamp. A row heading for row 1 is Hook Word (required). The next 5 rows are labeled D1 (optional), D2 (optional), D3 (optional), D4 (optional), and (optional). The last row is labeled T (optional).

An event record should be as short as possible. Many system events use only the hook word and time stamp. The data words should seldom be used because using them is less efficient and is intrusive. A long format allows the user to record a variable length of data. In this long form, the 16-bit data field of the hook word is converted to a length field that describes the length of the event record.

Trace Channels

The trace facility can accommodate up to eight simultaneous channels of trace-hook activity, which are numbered 0-7. Channel 0 is always used for system events, but application events can also use it. The other seven channels, called generic channels, can be used for tracing application-program activity.

When trace is started, channel 0 is used by default. A **trace -n *channel_number*** command starts trace to a generic channel. Use of the generic channels has some limitations:

- The interface to the generic channels costs more CPU time than the interface to channel 0 because of the need to distinguish between channels and because generic channels record variable-length records.
- Events recorded on channel 0 and on the generic channels can be correlated only by time stamp, not by sequence, so there may be situations in which it is not possible to determine which event occurred first.

Macros for Recording Trace Events

Macros to record each possible type of event record are defined in the `/usr/include/sys/trcmacos.h` file. The event IDs are defined in the `/usr/include/sys/trchkid.h` file. Include these two files in any program that is recording trace events.

The macros to record events on channel 0 with a time stamp are as follows:

```
TRCHKL0T(hw)
TRCHKL1T(hw,D1)
TRCHKL2T(hw,D1,D2)
TRCHKL3T(hw,D1,D2,D3)
TRCHKL4T(hw,D1,D2,D3,D4)
TRCHKL5T(hw,D1,D2,D3,D4,D5)
```

Similarly, to record events on channel 0 without a time stamp, use:

```
TRCHKL0(hw)
TRCHKL1(hw,D1)
TRCHKL2(hw,D1,D2)
TRCHKL3(hw,D1,D2,D3)
TRCHKL4(hw,D1,D2,D3,D4)
TRCHKL5(hw,D1,D2,D3,D4,D5)
```

The type field of the trace event record is set to the value that corresponds to the macro used, regardless of the value of those 4 bits in the `hw` parameter.

Only two macros record events to one of the generic channels (1-7). These are as follows:

```
TRCGEN(ch,hw,D1,len,buf)
TRCGENT(ch,hw,D1,len,buf)
```

These macros record in the event stream specified by the channel parameter (`ch`) a hook word (`hw`), a data word (`D1`) and `len` bytes from the user's data segment beginning at the location specified by `buf`.

Use of Event IDs

The event ID in a trace record identifies that record as belonging to a particular class of records. The event ID is the basis on which the trace mechanism records or ignores trace hooks, as well as the basis on which the **trcrpt** command includes or excludes trace records in the formatted report.

Event IDs are 12 bits (three hexadecimal digits) for a possible 4096 IDs. Event IDs that are reserved and shipped with code are permanently assigned to avoid duplication. To allow users to define events in their environments or during development, the range of event IDs from hex 010 through hex 0FF has been reserved for temporary use. Users can freely use IDs in this range in their own environment (that is, any set of systems within which the users are prepared to ensure that the same event ID is not used ambiguously).

Note: It is important that users who make use of this event range do not let the code leave their environment. If you ship code instrumented with temporary hook IDs to an environment in which you do not control the use of IDs, you risk collision with other programs that already use the same IDs in that environment.

Event IDs should be conserved because there are so few of them, but they can be extended by using the 16-bit Data Field. This yields a possible 65536 distinguishable events for every formal hook ID. The only reason to have a unique ID is that an ID is the level at which collection and report filtering are available in the trace facility.

A user-added event can be formatted by the **trcrpt** command if there is a stanza for the event in the specified trace format file. The trace format file is an editable ASCII file (see Syntax for Stanzas in the Trace Format File).

Examples of Coding and Formatting Events

The following example shows the use of trace events to time the execution of a program loop:

```
#include <sys/trcctl.h>
#include <sys/trcmacros.h>
#include <sys/trchkid.h>
char *ctl_file = "/dev/systrctl";
int ctld;
int i;
main()
{
    printf("configuring trace collection \n");
    if (trcstart("-ad")){
        perror("trcstart");
        exit(1);
    }

    printf("opening the trace device \n");
    if((ctld = open(ctl_file,0))<0){
        perror(ctl_file);
        exit(1);
    }

    printf("turning trace on \n");
    if(ioctl(ctld,TRCON,0)){
        perror("TRCON");
        exit(1);
    }

    for(i=1;i<11;i++){
        TRCHKLIT(HKWD_USER1,i);

        /* The code being measured goes here. The interval */
        /* between occurrences of HKWD_USER1 in the trace */
        /* file is the total time for one iteration.      */
    }

    printf("turning trace off\n");
    if(ioctl(ctld,TRCSTOP,0)){
        perror("TRCOFF");
        exit(1);
    }

    printf("stopping the trace daemon \n");
    if (trcstop(0)){
        perror("trcstop");
        exit(1);
    }
}
```

```

}
exit(0);
}

```

When you compile the sample program, you must link to the **librts.a** library as follows:

```
# xlc -O3 sample.c -o sample -l rts
```

HKWD_USER1 is event ID 010 hexadecimal (you can verify this by examining the **/usr/include/sys/trchkid.h** file). The report facility does not format the HKWD_USER1 event, unless rules are provided in the trace format file. The following example of a stanza for HKWD_USER1 could be used:

```

# User event HKWD_USER1 Formatting Rules Stanza
# An example that will format the event usage of the sample program
010 1.0 L=APPL "USER EVENT - HKWD_USER1" 02.0      \n \
      "The # of loop iterations =" U4      \n \
      "The elapsed time of the last loop = " \
      endtimer(0x010,0x010) starttimer(0x010,0x010)

```

When you enter the example stanza, do not modify the master format file **/etc/trcfmt**, but instead make a copy and keep it in your own directory (assume you name it **mytrcfmt**). When you run the sample program, the raw event data is captured in the default log file because no other log file was specified to the **trcstart()** subroutine. You can filter the output report to get only your events. To do this, run the **trcrpt** command as follows:

```
# trcrpt -d 010 -t mytrcfmt -O "exec=on" > sample.rpt
```

You can browse the **sample.rpt** file to see the result.

Syntax for Stanzas in the Trace Format File

The trace format file provides rules for presentation and display of the expected data for each event ID. This allows new events to be formatted without changing the report facility. Rules for new events are simply added to the format file. The syntax of the rules provides flexibility in the presentation of the data.

A trace format stanza can be as long as required to describe the rules for any particular event. The stanza can be continued to the next line by terminating the present line with a **** character. The fields are described in the *AIX 5L Version 5.1 Files Reference*.

Comments in the **/etc/trcfmt** file describe other format and macro possibilities and describe how a user can define additional macros.

Chapter 13. Using Performance Diagnostic Tool (PDT)

PDT attempts to identify performance problems automatically by collecting and integrating a wide range of performance, configuration, and availability data. The data is regularly evaluated to identify and anticipate common performance problems.

PDT assesses the current state of a system and tracks changes in workload and performance. It attempts to identify incipient problems and suggest solutions before the problems become critical.

For the most part, PDT functions with no required user input. PDT data collection and reporting are easily enabled, and then no further administrator activity is required. Periodically, data is collected and recorded for historical analysis, and a report is produced and mailed to the adm user. Normally, only the most significant apparent problems are recorded on the report. If there are no significant problems, that fact is reported. PDT can be customized to direct its report to a different user or to report apparent problems of a lower severity level.

This chapter contains the following main sections:

- Structure of PDT
- Scope of PDT Analysis
- Analyzing the PDT Report
- Installing and Enabling PDT
- Customizing PDT
- Responding to PDT Report Messages

Structure of PDT

As shown in the following illustration, the PDT application consists of three components:

- The *collection component* comprises a set of programs that periodically collect and record data.
- The *retention component* periodically reviews the collected data and discards data that is obsolete.
- The *reporting component* periodically produces a diagnostic report from the current set of historical data.

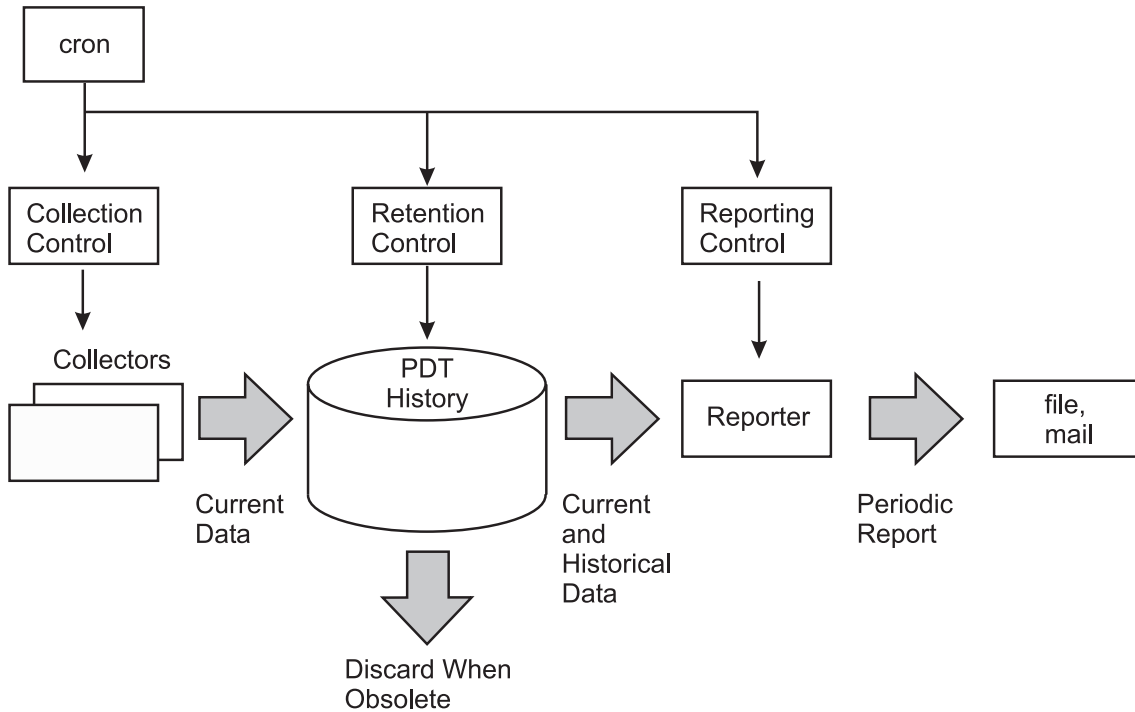

Figure 31. PDT Component Structure. This illustration is similar to an organizational chart with the three PDT application components at the top. They are; collection control, retention control and reporting control. A data path is drawn from collection control to collectors and then on to PDT History. A data path is drawn from retention control directly to PDT History. Data travels from Reporting control to the reporter and a periodic report is sent by file or mail. Data in PDT History can be discarded when it is obsolete or passed on to the reporter where periodic reports are sent by file or mail. All data is originated by the cron.

PDT considers various aspects of a system's configuration, availability, and delivered performance in making its assessment. In particular, areas of configuration imbalance are sought out (such as I/O-configuration balance, paging-configuration balance) as well as other configuration problems (for example, disks not allocated to volume groups). A wide variety of trending assessments is made, including file sizes, file-system sizes, paging-area usage, network delays, and workload-related delays.

Scope of PDT Analysis

PDT collects configuration, availability, workload, and performance data on a daily basis. This data is maintained in a historical record. Approximately one month's data is kept in this way. Also on a daily basis, PDT generates a diagnostic report, which is mailed to the adm user.

In addition to mailing the report, PDT stores a copy in the `/var/perf/tmp/PDT_REPORT` file. Before the new report is written, the previous report is renamed `/var/perf/tmp/PDT_REPORT.last`.

While many common system performance problems are of a specific nature (a system might have too little memory), PDT also attempts to apply some general concepts of well-performing systems to its search for problems. Some of these concepts, together with examples of their application to the operating system, are as follows:

- **Balanced Use of Resources**

In general, if there are several resources of the same type, then a balanced use of those resources produces better performance.

- Comparable numbers of physical volumes (disks) on each disk adapter
- Paging space distributed across multiple physical volumes
- Roughly equal measured load on different physical volumes

- Operation within Bounds

Resources have limits to their use. Trends attempting to exceed those limits should be detected and reported.

 - A disk drive cannot be used more than 100 percent of the time.
 - File and file-system sizes cannot exceed the allocated space.
- Identified Workload Trends

Trends can indicate a change in the nature of the workload, as well as increases in the amount of resource used:

 - Number of users logged on
 - Total number of processes
 - CPU-idle percentage
- Error-Free Operation

Hardware or software errors often produce performance problems:

 - Check the hardware and software error logs.
 - Report bad VMM pages.
- Changes Investigated

New workloads or processes that start to consume resources may be the first sign of a problem.
- Appropriate Setting of System Parameters

There are many parameters in a system, and they must be set correctly.

 - Is **maxuproc** set too low?
 - Are the memory-load-control-parameter settings too high or too low?

PDT normally uses less than 30 seconds of CPU time. Daily data collection takes several elapsed minutes.

Analyzing the PDT Report

A PDT report consists of several sections and differs depending on the severity level chosen (see PDT Severity Levels).

Header

The header section indicates the release number of PDT, the date the report was printed, the host from which the data was collected, and the range of dates of the data that fed the analysis. The content of this section is consistent for all severity levels.

An example of a report header follows:

```
Performance Diagnostic Facility 1.0
```

```
Report printed: Thu Feb 10 17:54:50 2000
```

```
Host name: itsosmp.itsc.austin.ibm.com
Range of analysis includes measurements
from: Hour 12 on Tuesday, February 8th, 2000
to: Hour 17 on Wednesday, February 9th, 2000
```

```
Notice: To disable/modify/enable collection or reporting
execute the pdt_config script as root
```

Alerts

The Alerts section focuses on identified violations of applied concepts and thresholds. The following subsystems may have problems when they appear in the Alerts section: file systems, I/O configuration, paging configuration, I/O balance, paging space, virtual memory, real memory, processes, and network.

For severity 1 levels, alerts focus on file systems, physical volumes, paging, and memory. If severity 2 or 3 is selected, information on configuration and processes is added.

An example of an Alerts section follows:

```
----- Alerts -----  
  
I/O CONFIGURATION  
- Note: volume hdisk1 has 872 MB available for allocation  
  while volume hdisk0 has 148 MB available  
- Physical volume hdisk2 is unavailable; (in no volume group)  
  
PAGING CONFIGURATION  
- Physical Volume hdisk2 (type: SCSI) has no paging space defined  
- Paging space paging00 on volume group rootvg is fragmented  
- Paging space paging01 on volume group uservg is fragmented  
  
I/O BALANCE  
- Phys. volume hdisk2 is not busy  
  volume hdisk2, mean util. = 0.00 %  
  
PROCESSES  
- First appearance of 20642 (cpubound) on top-3 cpu list  
  (cpu % = 24.10)  
- First appearance of 20106 (eatmem) on top-3 memory list  
  (memory % = 8.00)  
  
FILE SYSTEMS  
- File system hd2 (/usr) is nearly full at 100 %  
  
NETWORK  
- Host ah6000e appears to be unreachable.  
  (ping loss % = 100) and has been for the past 4 days
```

The I/O configuration indicates that the data is not well-distributed through the disks and that hdisk2 is not used at all. Add this disk to a volume group and define a paging space on it. The existing paging areas are fragmented and should be reorganized; for example, with the **reorgvg** command. The I/O balance section shows that hdisk2 is not busy, because hdisk2 has not been assigned to a volume group.

In most systems, **/usr** file system use is nearly 100 percent. Usually this is not a problem, but system administrators should check if there is any application writing data to this file system.

Upward and Downward Trends

PDT employs a statistical technique to determine whether there is a trend in a series of measurements. If a trend is detected, the slope of the trend is evaluated for its practical significance. An estimated date at which a file system or the page space will be full is provided, based on an assumption of continued linear growth. For upward trends, the following items are evaluated: files, file systems, hardware and software errors, paging space, processes, and network. For downward trends, the following can be reported: files, file systems, and processes.

An example of an Upward Trends and Downward Trends section follows:

```
----- Upward Trends -----  
  
FILES  
- File (or directory) /usr/adm/wtmp SIZE is increasing  
  now, 20 KB and increasing an avg. of 2163 bytes/day
```

- File (or directory) /var/adm/ras/ SIZE is increasing now, 677 KB and increasing an avg. of 11909 bytes/day

FILE SYSTEMS

- File system hd9var (/var) is growing now, 17.00 % full, and growing an avg. of 0.38 %/day
- File system lv00 (/usr/vice/cache) is growing now, 51.00 % full, and growing an avg. of 4.64 %/day
At this rate, lv00 will be full in about 9 days

PAGE SPACE

- Page space hd6 USE is growing now, 81.60 MB and growing an avg. of 2.69 MB/day
At this rate, hd6 will be full in about 29 days

ERRORS

- Software ERRORS; time to next error is 0.958 days

----- Downward Trends -----

PROCESSES

- Process 13906 (maker4X.e) CPU use is declining now 1.20 % and declining an avg. of 0.68 % per day
- Process 13906 (maker4X.e) MEMORY use is declining now 13.00 and declining an avg. of 0.98 % per day

FILES

- File (or directory) /tmp/ SIZE is declining

FILE SYSTEMS

- File system hd3 (/tmp) is shrinking

The /usr/adm/wtmp is liable to grow unbounded. If it gets too large, login times can increase. In some cases, the solution is to delete the file. In most cases, it is important to identify the user causing the growth and work with that user to correct the problem.

The error log file is located in the directory /var/adm/ras. The ERRORS section shows that the number of software errors is increasing, which is most likely the reason why the directory size increased. Check the error log, verify which application is in error, and correct the problem.

The increase in the use of paging space might be due to a process with a memory leak. That process should be identified and the application fixed. However, the paging space might not be well-dimensioned and may need to be enlarged.

System Health

The System Health section provides an assessment of the average number of processes in each process state on the system. Additionally, workload indicators are noted for any upward trends.

An example of a System Health section follows:

```
----- System Health -----

SYSTEM HEALTH
- Current process state breakdown:
  75.00 [ 100.0 %] : active
  0.40 [ 0.5 %] : swapped
  75.00 = TOTAL
  [based on 1 measurement consisting of 10 2-second samples]
```

Summary

The severity level of the current report is listed, as well as an indication as to whether more details are available at higher severity levels.

An example of a Summary section follows:

```
----- Summary -----
This is a severity level 3 report
No further details available at severity levels > 3
```

Any message (excluding header and summary information) occurring in the PDT report should be investigated. The indicated problem should be corrected or an explanation for the condition obtained. Possible responses to specific messages are covered in Responding to PDT Report Messages.

Installing and Enabling PDT

PDT is installed through the **installp** command as the **bos.perf.diag_tool** option of the operating system version 4 BOS licensed program.

PDT must be enabled in order to begin collecting data and writing reports. Enable PDT by executing the **/usr/sbin/perf/diag_tool/pdt_config** script. Only the root user is permitted to run this script. When executed, the following message is displayed:

```
# /usr/sbin/perf/diag_tool/pdt_config
_____PDT customization menu_____

1) show current PDT report recipient and severity level
2) modify/enable PDT reporting
3) disable PDT reporting
4) modify/enable PDT collection
5) disable PDT collection
6) de-install PDT
7) exit pdt_config
Please enter a number:
```

When you respond with 4, default PDT collection and reporting is enabled. The crontab entry for user adm is updated to add the PDT entries (see Modifying the Collection, Retention, and Reporting Times for more detail). The entries execute a shell script called **Driver_** in the **/usr/sbin/perf/diag_tool** directory. This script is passed three different parameters, each representing a collection profile, at three different collection times.

To terminate the **pdt_config** program, respond with 7.

To disable collection, respond with 5.

Customizing PDT

Certain aspects of PDT can be customized. For example, any user can be designated as the regular recipient of PDT reports, and the retention period for data in PDT's historical record can be modified. All customization is performed either by modifying one of the PDT files in the directory **/var/perf/cfg/diag_tool/** or by executing the **/usr/sbin/perf/diag_tool/pdt_config** script.

It is recommended that no changes be made until after PDT has produced several reports, and a certain familiarity with PDT has been acquired.

Changing the PDT Report Recipient and Severity Level

By default, PDT reports are generated with severity level 1 with only the most serious problems identified. There are other severity levels (2 and 3) at which more detailed information is frequently available. Further, whenever a PDT report is produced, it is mailed to the adm user. You can choose to have the report mailed elsewhere or not mailed at all.

Both of these parameters are controlled with the **/usr/sbin/perf/diag_tool/pdt_config** script. The following dialog changes the user and the severity level:

```
# /usr/sbin/perf/diag_tool/pdt_config
_____PDT customization menu_____

1) show current PDT report recipient and severity level
```

```
2) modify/enable PDT reporting
3) disable      PDT reporting
4) modify/enable PDT collection
5) disable      PDT collection
6) de-install   PDT
7) exit pdt_config
Please enter a number: 1
```

```
current PDT report recipient and severity level
adm 1
```

```
_____PDT customization menu_____
```

```
1) show current  PDT report recipient and severity level
2) modify/enable PDT reporting
3) disable      PDT reporting
4) modify/enable PDT collection
5) disable      PDT collection
6) de-install   PDT
7) exit pdt_config
Please enter a number: 2
```

```
enter id@host for recipient of report : rsmith
enter severity level for report (1-3): 2
```

```
report recipient and severity level
rsmith 2
```

```
_____PDT customization menu_____
```

```
1) show current  PDT report recipient and severity level
2) modify/enable PDT reporting
3) disable      PDT reporting
4) modify/enable PDT collection
5) disable      PDT collection
6) de-install   PDT
7) exit pdt_config
Please enter a number: 1
```

```
current PDT report recipient and severity level
rsmith 2
```

```
_____PDT customization menu_____
```

```
1) show current  PDT report recipient and severity level
2) modify/enable PDT reporting
3) disable      PDT reporting
4) modify/enable PDT collection
5) disable      PDT collection
6) de-install   PDT
7) exit pdt_config
Please enter a number: 7
```

In the preceding example, the recipient is changed to user rsmith, and the severity is changed to 2. This means that user rsmith will receive the PDT report, and that both severity 1 and 2 messages will be included. Note the use of option 1 to determine the current PDT report recipient and report severity level.

The user and security level could also be changed directly in the `/var/perf/cfg/diag_tool/reporting.list` file.

To terminate reporting (but allow collection to continue), option 3 is selected, for example:

```
# /usr/sbin/perf/diag_tool
```

```

reporting has been disabled (file .reporting.list not found).

PDT Severity Levels

The following lists indicate the possible problems associated with each severity level. Remember that selecting severity *n* results in the reporting of all problems of severity less than or equal to *n*.

Severity 1 Problems

- Journalled File System (JFS) becomes unavailable
- JFS nearly full
- Physical volume not allocated to a volume group
- All paging spaces defined on one physical volume
- System appears to have too little memory for current workload
- Page space nearly full
- Possible problems in the settings of load control parameters
- VMM-detected bad memory frames
- Any host in **.nodes** becomes unreachable

Severity 2 Problems

- Imbalance in the I/O configuration (for example, disks per adapter)
- Imbalance in allocation of paging space on physical volumes with paging space
- Fragmentation of a paging space in a volume group
- Significant imbalance in measured I/O load to physical volumes
- New process is identified as a heavy memory or CPU consumer
- A file in **.files** exhibits systematic growth (or decline) in size
- A file system or page space exhibits systematic growth (or decline) in space utilization
- A host in **.nodes** exhibits degradation in **ping** delays or packet loss percentage
- A **getty** process consumes too much CPU time
- A process with high CPU or memory consumption exhibits systematic growth (or decline) in resource use
- **maxuproc** indicated as being possibly too low for a particular user ID
- A WORKLOAD TRACKING indicator shows an upward trend

Severity 3 Messages

Severity 3 messages provide additional detail about problems identified at severity levels 1 and 2. This includes the data-collection characteristics, such as number of samples, for severity 1 and 2 messages.

Obtaining a PDT Report on Demand

As an alternative to using the periodic report, any user can request a current report from the existing data by executing `/usr/sbin/perf/diag_tool/pdt_report SeverityNum`. The report is produced with the given severity (if none is provided, *SeverityNum* defaults to 1) and written to standard output. Generating a report in this way does not cause any change to the `/var/perf/tmp/PDT_REPORT` or to `/var/perf/tmp/PDT_REPORT.last` files.

Modifying the List of Files Monitored by PDT

PDT analyzes files and directories for systematic growth in size. It examines only those files and directories listed in the file `/var/perf/cfg/diag_tool/files`. The format of the `.files` file is one file or directory name per line. The default content is as follows:

```
/usr/adm/wtmp
/var/spool/qdaemon/
/var/adm/ras/
/tmp/
```

You can use an editor to modify this file to track files and directories that are important to your system.

Modifying the List of Hosts That PDT Monitors

PDT tracks the average ping delay to hosts whose names are listed in the `/var/perf/cfg/diag_tool.nodes` file. This file is not shipped with PDT (which means that no host analysis is performed by default), but may be created by the administrator. The format of the `.nodes` file is one host name per line in the file. For example, to monitor nodes `chuys` and `hulahut`, the file `.nodes` would be as follows:

```
chuys
hulahut
```

Changing the Historical-Record Retention Period

Periodically, a retention shell script is run that discards entries in the PDT historical record that are older than the designated retention period. The retention of all data is governed by the same retention policy. This policy is described in the `/var/perf/cfg/diag_tool.retention.list` file. The default `.retention.list` content is as follows:

```
* * * 35
```

which causes all data to be retained no more than 35 days. The number 35 can be replaced by any unsigned integer.

PDT uses the historical record to assess trends and identify system changes. Extending the retention period increases the scope of this analysis, but at the cost of additional disk storage and PDT processing time.

The PDT historical record is maintained in `/var/perf/tmp/.SM`. The retention script creates a copy of this file in `/var/perf/tmp/.SM.last` prior to performing the retention operation. In addition, historical data that is discarded is appended to `/var/perf/tmp/.SM.discards`.

The existence of `/var/perf/tmp/.SM.last` provides limited backup, but the administrator should ensure that the `/var/perf/tmp/.SM` file is regularly backed up. If the file is lost, PDT continues to function, but without the historical information. Over time, the historical record will grow again as new data is collected.

Modifying the Collection, Retention, and Reporting Times

Collection, reporting and retention are driven by three entries in the user adm **cron** table. Collection occurs on every weekday at 9 a.m (Driver_ daily). Reporting occurs every weekday at 10 a.m (Driver_ daily2). The retention analysis is performed once a week, on Saturday evening at 9 p.m (Driver_ offweekly). The following files are used:

/var/perf/cfg/diag_tool/collection.control

Handles collection information

/var/perf/cfg/diag_tool/retention.control

Handles retention information

/var/perf/cfg/diag_tool/reporting.control

Handles reporting information

The cron entries (created by executing the **/usr/sbin/perf/diag_tool/pdt_config** script and selecting option 2) are shown below:

```
0 9 * * 1-5 /usr/sbin/perf/diag_tool/Driver_ daily
0 10 * * 1-5 /usr/sbin/perf/diag_tool/Driver_ daily2
0 21 * * 6 /usr/sbin/perf/diag_tool/Driver_ offweekly
```

The default times can be changed by altering the crontab for user adm.

Modifying the Thresholds

The file **/var/perf/cfg/diag_tool/thresholds** contains the thresholds used in analysis and reporting. These thresholds, listed below, have an effect on PDT report organization and content.

- **DISK_STORAGE_BALANCE**

The SCSI controllers having the largest and the smallest disk storage are identified. This is a static size, not the amount allocated or free. If the difference (in MB) between these two controllers exceeds **DISK_STORAGE_BALANCE**, a message is reported:

```
SCSI Controller %s has %.01f MB more storage than %s
```

The default value for **DISK_STORAGE_BALANCE** is 800. Any integer value between 0 and 10000 is valid.

- **PAGING_SPACE_BALANCE**

The paging spaces having the largest and the smallest areas are identified. If the difference (in MB) between these two exceeds **PAGING_SPACE_BALANCE**, a message is reported. The default value is 4. Any integer value between 0 and 100 is accepted. This threshold is presently not used in analysis and reporting.

- **NUMBER_OF_BALANCE**

The SCSI controllers having the largest and the least number of disks attached are identified. If the difference between these two counts exceeds **NUMBER_OF_BALANCE**, a message is reported:

```
SCSI Controller %s has %.01f more disks than %s
```

The default value is 1. It can be set to any integer value in the range of 0 to 10000.

The same type of test is performed on the number of paging areas on each physical volume:

```
Physical Volume %s has %.01f paging areas, while Physical Volume %s has only %.01f
```

- **MIN_UTIL**

Applies to process utilization. Changes in the top three CPU consumers are only reported if the new process had a utilization in excess of **MIN_UTIL**.

```
First appearance of %s (%s) on top-3 cpu list
```

The same threshold applies to changes in the top-three memory consumers list:

First appearance of %s (%s) on top-3 memory list

The default value is 3. Any integer value from 0 to 100 is valid.

- **FS_UTIL_LIMIT**

Applies to journaled file system utilization. If the file system has a percentage use above FS_UTIL_LIMIT, a message is reported:

File system %s (%s) is nearly full at %.01f %%

The same threshold is applied to paging spaces:

Paging space %s is nearly full at %.01f %%

The default value is 90 percent. Any integer value between 0 and 100 is accepted.

Special attention should be given to */*, */var*, and */tmp* file systems. The operating system uses these areas for normal operation. If there remains no space in one of these, the behavior of the system is unpredictable. Error messages are provided when the execution of commands fails, but to detect these file system problems earlier, decrease FS_UTIL_LIMIT to 70 or 80 percent.

- **MEMORY_FACTOR**

The objective is to determine if the total amount of memory is adequately backed up by paging space. If real memory is close to the amount of used paging space, then the system is likely paging and would benefit from the addition of memory.

The formula is based on experience and actually compares MEMORY_FACTOR * memory with the average used paging space.

The current default is 0.9. By decreasing this number, a warning is produced more frequently:

System has %.01f MB memory; may be inadequate.

Increasing this number eliminates the message altogether. It can be set anywhere between 0.001 and 100.

- **TREND_THRESHOLD**

Used in all trending assessments. It is applied after a linear regression is performed on all available historical data. This technique basically draws the best line among the points. The slope of the fitted line must exceed the last_value * TREND_THRESHOLD.

File system %s (%s) is growing,
now, %.21f %% full, and growing an avg. of %.21f %%/day

The objective is to try to ensure that a trend, however strong its statistical significance, has some practical significance.

For example, if we determine that a file system is growing at X MB a day, and the last_value for the file system size is 100 MB, we require that X exceeds 100 MB * TREND_THRESHOLD to be reported as a trend of practical significance. The default value is 0.01; so a growth rate of 1 MB per day would be required for reporting. The threshold can be set anywhere between 0.00001 and 100000.

This threshold assessment applies to trends associated with:

- CPU use by a top-three process
- Memory use by a top-three process
- Size of files indicated in the **.files** file
- Journaled file systems
- Paging spaces
- Hardware and software errors
- Workload indicators
- Processes per user

- Ping delay to nodes in the **.nodes** file
- Percentage of packet loss to nodes in the **.nodes** file
- **EVENT_HORIZON**

Used also in trending assessments. For example, in the case of file systems, if there is a significant (both statistical and practical) trend, the time until the file system is 100 percent full is estimated. If this time is within **EVENT_HORIZON**, a message is reported:

At this rate, %s will be full in about %.01f days

The default value is 30, and it can be any integer value between 0 and 100000.

This threshold applies to trends associated with:

- File Systems (JFS)
- Page Spaces

PDT Error Reporting

Errors can occur within each of the different PDT components. In general, an error does not terminate PDT. Instead, a message is output to the PDT standard error file, **/var/perf/tmp/stderr**. That phase of processing then terminates.

Users experiencing unexpected behavior, such as the PDT report not being produced as expected, should examine the **/var/perf/tmp/stderr** file.

Uninstalling PDT

It is not possible to uninstall PDT directly using the **pdt_config** command, but if option 6 is requested, a message describes the steps necessary to remove PDT from the system:

```
# /usr/sbin/perf/diag_tool/pdt_config
```

```
_____PDT customization menu_____
```

- 1) show current PDT report recipient and severity level
- 2) modify/enable PDT reporting
- 3) disable PDT reporting
- 4) modify/enable PDT collection
- 5) disable PDT collection
- 6) de-install PDT
- 7) exit pdt_config

```
Please enter a number: 6
```

```
PDT is installed as package bos.perf.diag_tool in the bos lpp.  
Use the installp facility to remove the package
```

Responding to PDT Report Messages

PDT identifies many types of problems. Responses to these indications depend on the individual organization's available resources and set of priorities. The following samples suggest some possibilities (cmds stands for commands):

Problem:

JFS file system becomes unavailable

Response:

Investigate why file system is unavailable. The file system could have been removed.

Useful cmds:

lsfs (to determine file system status)

Problem:

JFS file system nearly full

Response:

This problem could be caused by large or core files within the file system. Look for large files in the file system, possibly caused by a runaway process. Attempt to identify the process or user that generated those files. The system administrator should also verify if PDT report indicates a long-term growth trend for this file system. Has this file system exhibited long-term growth trend (examine the rest of the PDT report or past PDT reports)?

Useful cmds:

du, ls

Problem:

Physical volume not allocated to a volume group

Response:

If a physical volume is not allocated to a volume group, the operating system has no access to this disk, and its space is being wasted. Use the **lspv** command to ensure that the disk is not allocated to any volume group, and if not, use the **extendvg** command to add the disk to a volume group.

Useful cmds:

lspv (to confirm that the volume is not allocated)
smitty (to manipulate volume groups)

Problem:

All paging spaces defined on one physical volume

Response:

The system has more than one physical volume, yet all paging space is defined on a single volume. If the system experiences paging, this configuration will result in reduced performance. A better I/O throughput could be achieved if the paging space is split equally among all physical volumes. Only one paging space should be defined per physical volume because the system will only have access to one at a time. Use SMIT to create, modify, activate, or deactivate the paging areas.

Useful cmds:

smitty (to modify paging spaces)

Problem:

Apparently too little memory for current workload

Response:

If the system is paging heavily, more memory may be required on the system for good performance. The **vmstat** or **svmon** commands provide further details about the paging activity. See The vmstat Command, and The svmon Command, for more information on those commands.

Useful cmds:

lsps -a, vmstat, svmon

Problem:

Page space nearly full

Response:

The system's paging space may not be well dimensioned and may need to be enlarged, unless the problem is due to a process with a memory leak, in which case that process should be identified and the application fixed. For systems up to 256 MB of memory, the paging space should be twice the size of real memory. For memories larger than 256 MB, use the following formula:

total paging space = 512 MB + (memory size - 256 MB) * 1.25

Useful cmds:

ps auctg (to examine process activity)
smitty (to modify page space characteristics)

Problem:

Possible problems in the settings of load control parameters

Response:

The memory-load-control parameters are evaluated in relation to current paging activity. For example, if thrashing is occurring and load control is not enabled, it may be appropriate to enable load control. This situation might also be due to inappropriate load-control parameter settings. Use the **schedtune** command to view or alter the configuration. Refer to Tuning VMM Memory Load Control with the schedtune Command, for further details.

Useful cmds

schedtune

Problem:

VMM-detected bad memory frames

Response:

It might be necessary to have the memory analyzed. Compare the amount of installed memory with the memory actually accessible. If the latter is less than the former, then bad memory has been identified.

You can use **/usr/sbin/perf/diag_tool/getvmparms** to examine the value of numframes to determine the actual number of valid 4 KB memory frames.

Useful cmds:

lscfg | grep mem (to obtain installed memory size in MB)

Problem:

Any host in .nodes becomes unreachable

Response:

Determine if problem is with current host (has a change in the **/etc/hosts** file been made?), with the remote host (is it down?), or with the network (is the nameserver down?).

The problem may be due to name resolution. Either Domain Name Service (DNS) configuration files or **/etc/hosts** should be checked depending on the type of name resolution being used at the environment.

Use the **ping** command to check if the machine has access to other nodes in the same network. The remote node might be down. If it cannot access any other node, cables and connections should be verified, as well as the routing table of the current machine. Verify cables and connections by executing the **netstat -r** command.

Useful cmds:

ping, netstat

Problem:

Imbalance in the I/O configuration (number of disks per adapter)

Response:

The number of disks per adapter should be equal whenever possible, to prevent one adapter from being overloaded. A guideline is to have no more than four devices per adapter, especially if the access to the disks is mostly sequential. Consider moving disks around so that an individual adapter is not overloaded.

Useful cmds:

lscfg (to examine the current configuration)

iostat (to determine if the actual load on the adapters is out of balance)

Problem:

Imbalance in allocation of paging space on physical volumes with paging space

Response:

A substantial imbalance in the sizes of paging spaces can cause performance problems. The

paging space should be equally distributed throughout the disks. Consider making paging spaces the same size, except for a few extra megabytes on the primary paging space (hd6).

Useful cmds:
smitty pgspace

Problem:
Fragmentation of a paging space in a volume group

Response:
Paging performance is better if paging areas are contiguous on a physical volume. However, when paging areas are enlarged, it is possible to create fragments that are scattered across the disk surface. Use the **reorgvg** command to reorganize the paging spaces.

Useful cmds:
lspv -p hdiskn for each physical volume in the volume group. Look for more than one PP Range with the same LVNAME and a TYPE of paging.

Problem:
Significant imbalance in measured I/O load to physical volumes

Response:
The data is most likely not well-distributed throughout the disks. Use the **iostat** command to obtain information about the I/O activity of each disk (refer to Assessing Disk Performance with the iostat Command). A disk should not be utilized more than 40 percent over a period of time. If one physical volume seems to be getting little I/O activity, consider moving data from busier physical volumes onto less busy volumes. In general, the more evenly the I/O is distributed, the better the performance. Distribute data throughout the disks in a manner that balances I/O. Use the **filemon** command to obtain information about the most accessed files and file systems. This can be a good starting point in reorganizing the data. Refer to Detailed I/O Analysis with the filemon Command, for more information on the **filemon** command.

Useful cmds:
iostat -d 2 20 (to view the current distribution of I/O across physical volumes)

Problem:
New process is a heavy consumer of memory or CPU

Response:
Top CPU and memory consumers are regularly identified by PDT. If any of these processes have not been detected before, they are highlighted in a problem report. Examine these processes for unusual behavior. Note that PDT simply looks at the process ID. If a known heavy user terminates, then is resumed (with a different process ID), it will be identified here as a *new* heavy user.

Useful cmds:
ps aux (to view all processes and their activity)

Problem:
Any file in .files exhibits systematic growth (or decline) in size

Response:
Look at the current size. Consider the projected growth rate. What user or application is generating the data? For example, the **/var/adm/wtmp** file is liable to grow unbounded. If it gets too large, login times can increase. In some cases, the solution is to delete the file. In most cases, it is important to identify the user causing the growth and work with that user to correct the problem.

Useful cmds:
ls -al (to view file/directory sizes)

Problem:
Any file system or paging space exhibits systematic growth (or decline) in space used

Response:

Consider the projected growth rate and expected time until exceeding the available space. Analyze the problem by identifying which user or process is generating the data. It may be necessary to enlarge the file system (or page space). On the other hand, the growth may be an undesirable effect (for example, a process having a memory leak).

Useful cmds:

smitty (to manipulate file systems/page spaces)
ps auxg, svmon (to view process virtual memory activity)
filemon (to view file system activity)

Problem:

Degradation in ping response time or packet loss percentage for any host in .nodes

Response:

There is probably a performance problem in the host or in the network. Is the host in question experiencing performance problems? Is the network having performance problems?

Useful cmds:

ping, rlogin, rsh (to time known workloads on remote host)

Problem:

A getty process that consumes too much CPU time

Response:

Getty processes that use more than just a few percent of the CPU may be in error. It is possible in certain situations for these processes to consume system CPU, even though no users are actually logged in. In general, the solution is to terminate the process.

Useful cmds:

ps auxg (to see how much CPU is being used)

Problem:

A process that is a top consumer of CPU or memory resources exhibits systematic growth or decline in consumption

Response:

Known large consumers of CPU and memory resources are tracked over time to see if their demands grow. As major consumers, a steady growth in their demand is of interest from several perspectives. If the growth is normal, this represents useful capacity planning information. If the growth is unexpected, then evaluate the workload for a change (or a chronic problem, such as a memory leak). Use the **vmstat** and **svmon** commands while the process is running to gather more information on its behavior.

Useful cmds:

ps auxg, vmstat, svmon

Problem:

maxuproc indicated as being possibly too low for a particular userid

Response:

It is likely that this user is reaching the **maxuproc** threshold. **maxuproc** is a systemwide parameter that limits the number of processes that nonroot users are allowed to have simultaneously active. If the limit is too low, the user's work can be delayed or terminated. On the other hand, the user might be accidentally creating more processes than needed or appropriate. Further investigation is warranted in either case. Consult the user in order to clearly understand what is happening.

Useful cmds:

lsattr -E -l sys0 | grep maxuproc to determine the current value of **maxuproc** (although it is also

reported directly in the PDT message).

chdev -l sys0 -a maxuproc=100 to change **maxuproc** to 100 (for example). Root user authority is required.

Problem:

A WORKLOAD TRACKING indicator shows an upward trend

Response:

The response depends on which workload indicator shows the trend:

loadavg

Refers to 15-minute load average. In general, it indicates that the level of contention in the system is growing. Examine the rest of the PDT report for indicators of system bottlenecks (for example, substantial page space use might indicate a memory shortage; I/O imbalances might indicate that the I/O subsystem requires attention).

nusers

Shows that the number of logged-on users on the system is growing. This is important from a capacity planning perspective. Is the growth expected? Can it be explained?

nprocesses

Indicates that the total number of processes on the system is growing. Are there users reaching the **maxuproc** limitation? Perhaps there are "runaway" applications forking too many processes.

STAT_A

Number of active processes. A trend here indicates processes are spending more time waiting for the CPU.

STAT_W

Number of swapped processes. A trend here indicates that processes are contending excessively for memory.

STAT_Z

Number of zombie processes. Zombies should not stay around for a long period of time. If the number of zombies on a system is growing, this may be cause for concern.

STAT_I

Number of idle processes.

STAT_T

Number of processes stopped after receiving a signal. A trend here might indicate a programming error.

STAT_x

Number of processes reported by the **ps** command as being in state *x*, where *x* is a state not listed in the other **STAT_*** states. The interpretation of a trend depends on the meaning of the character *x*. Refer to Using the ps Command, for more information on the **ps** command.

cp

Time required to copy a 40 KB file. An upward trend in the time to do a file copy suggests degradation in the I/O subsystem.

idle_pct_cpu0

Idle percentage for processor 0. An upward trend in the idle percentage might indicate increased contention in non-CPU resources such as paging or I/O. Such an increase suggests the CPU resource is not being well-utilized.

idle_pct_avg

Average idle percentage for all processors. An upward trend in the idle percentage might indicate increased contention in non-CPU resources such as paging or I/O. Such an increase suggests the CPU resource is not being well-utilized.

Chapter 14. Reporting Performance Problems

If you believe that you have found a possible performance problem in the operating system, you can use tools and procedures for reporting the problem and supplying problem-analysis data. These tools are intended to ensure that you get a prompt and accurate response, with a minimum of effort and time on your part.

The main sections in this topic are:

- Measuring the Baseline
- Reporting a Performance Problem
- Using the Problem-Analysis Data Collected

Measuring the Baseline

Performance problems are often reported immediately following some change to system hardware or software. Unless there is a pre-change baseline measurement with which to compare post-change performance, quantification of the problem is impossible.

Having the Performance Diagnostic Tool (PDT) installed and operational (see Chapter 13. Using Performance Diagnostic Tool (PDT)) provides a baseline of overall system performance.

Changes to any of the following can affect performance:

- Hardware configuration - Adding, removing, or changing configurations such as how the disks are connected
- Operating system - Installing or updating a fileset, installing PTFs, and changing parameters
- Applications - Installing new versions and fixes
- Applications - Configuring or changing data placement
- Application tuning
- Tuning options in the operating system, RDBMS or an application
- Any changes

One option is to run the measurement before and after each change. The alternative is running the measurements at regular intervals (for example, once a month) and save the output. When a problem is found, the previous capture can be used for comparison. It is worth collecting a series of outputs in order to support the diagnosis of a possible performance problem.

To maximize performance diagnosis, collect data for various periods of the working day, week, or month when performance is likely to be an issue. For example, you might have workload peaks as follows:

- In the middle of the mornings for online users
- During a late-night batch run
- During the end-of-month processing
- During major data loads

Use measurements to collect data for each of these peaks in workload, because a performance problem might only cause problems during one of these periods and not during other times.

Note: Any measurement has an impact on the performance of the system being measured.

Reporting a Performance Problem

You should report operating system performance problems to IBM support. Use your normal software problem-reporting channel. If you are not familiar with the correct problem-reporting channel for your organization, check with your IBM representative.

What is a Performance Problem?

Support personnel need to determine when a reported problem is a functional problem or a performance problem. When an application, a hardware system, or a network is not behaving correctly, this is referred to as a *functional problem*. For example, an application or a system with a memory leak has a functional problem.

Sometimes functional problems lead to performance problems; for example, when the functions are being achieved, but the speed of the functions are slow. In these cases, rather than tune the system, it is more important to determine the root cause of the problem and fix it. Another example would be when communication is slowed because of networks or name servers that are down.

Performance Problem Description

Support personnel often receive problem reports stating that someone has a performance problem on the system and providing some data analysis. This information is insufficient to accurately determine the nature of a performance problem. The data might indicate 100 percent CPU utilization and a high run queue, but that may have nothing to do with the cause of the performance problem.

For example, a system might have users logged in from remote terminals over a network that goes over several routers. The users report that the system is slow. Data might indicate that the CPU is very heavily utilized. But the real problem could be that the characters get displayed after long delays on their terminals due to packets getting lost on the network (which could be caused by failing routers or overloaded networks). This situation might have nothing to do with the CPU utilization on the machine. If on the other hand, the complaint was that a batch job on the system was taking a long time to run, then CPU utilization or I/O bandwidth might be related.

Always obtain as much detail as possible before you attempt to collect or analyze data, by asking the following questions regarding the performance problem:

- Can the problem be demonstrated by running a specific command or reconstructing a sequence of events? (for example: **ls /slow/fs** or **ping xxxxx**). If not, describe the least complex example of the problem.
- Is the slow performance intermittent? Does it get slow, but then disappear for a while? Does it occur at certain times of the day or in relation to some specific activity?
- Is everything slow or only some things?
- What aspect is slow? For example, time to echo a character, or elapsed time to complete a transaction, or time to paint the screen?
- When did the problem start occurring? Was the situation the same ever since the system was first installed or went into production? Did anything change on the system before the problem occurred (such as adding more users or migrating additional data to the system)?
- If client/server, can the problem be demonstrated when run just locally on the server (network versus server issue)?
- If network related, how are the network segments configured (including bandwidth such as 10 Mb/sec or 9600 baud)? Are there any routers between the client and server?
- What vendor applications are running on the system, and are those applications involved in the performance issue?
- What is the impact of the performance problem on the users?

Reporting the Problem

When someone reports a performance problem, it is not enough just to gather data and then analyze it. Without knowing the nature of the performance problem, you might waste a lot of time analyzing data which may have nothing to do with the problem being reported.

Before you involve support personnel to report a problem, prepare in advance the information that you will be asked to supply to facilitate the problem to be investigated. Your local support personnel will attempt to quickly solve your performance problem directly with you.

Three further ways you can help to get the problem resolved faster are:

1. Provide a clear written statement of a simple specific instance of problem, but be sure to separate the symptoms and facts from the theories, ideas and your own conclusions. PMRs that report "the system is slow" require extensive investigation to determine what you mean by slow, how it is measured, and what is acceptable performance.
2. Provide information about everything that has changed on the system in the weeks before the problem. Missing something that changed can block a possible investigation path and will only delay finding a resolution. If all the facts are available, the performance team can quickly eliminate the unrelated ones.
3. Use the correct machine to supply information. In very large sites it is easy to accidentally collect the data on the wrong machine. This makes it very hard to investigate the problem.

When you report the problem, supply the following basic information:

- A problem description that can be used to search the problem-history database to see if a similar problem has already been reported.
- What aspect of your analysis led you to conclude that the problem is due to a defect in the operating system?
- What is the hardware and software configuration in which the problem is occurring?
 - Is the problem confined to a single system, or does it affect multiple systems?
 - What are the models, memory sizes, as well as number and size of disks on the affected systems?
 - What kinds of LAN and other communications media are connected to the systems?
 - Does the overall configuration include those for other operating systems?
- What are the characteristics of the program or workload that is experiencing the problem?
 - Does an analysis with the **time**, **iostat**, and **vmstat** commands indicate that it is CPU-limited or I/O-limited?
 - Are the workloads being run on the affected systems: workstation, server, multiuser, or a combination?
- What are the performance objectives that are not being met?
 - Is the primary objective in terms of console or terminal response time, throughput, or real-time responsiveness?
 - Were the objectives derived from measurements on another system? If so, what was its configuration?

If this is the first report of the problem, you will receive a PMR number for use in identifying any additional data you supply and for future reference.

Using the Problem-Analysis Data Collected

Include all of the following items when the supporting information for the PMR is first gathered:

- A means of reproducing the problem
 - If possible, a program or shell script that demonstrates the problem should be included.
 - At a minimum, a detailed description of the conditions under which the problem occurs is needed.

- The application experiencing the problem
 - If the application is, or depends on, any software product, the exact version and release of that product should be identified.
 - If the source code of a user-written application cannot be released, the exact set of compiler parameters used to create the executable program should be documented.

Chapter 15. Application Tuning

Before spending a lot of effort to improve the performance of a program, use the techniques in this chapter to help determine how much its performance can be improved and to find the areas of the program where optimization and tuning will have the most benefit. For an extensive discussion of these techniques, see *Optimization and Tuning Guide for XL Fortran, XL C and XL C++*. Also see *Designing and Implementing Efficient Programs* for additional hints and tips.

In general, the optimization process involves several steps:

- Some tuning involves changing the source code, for example, by reordering statements and expressions. This technique is known as *hand tuning*.
- For FORTRAN and C programs, optimizing preprocessors are available to tune and otherwise transform source code before it is compiled. The output of these preprocessors is FORTRAN or C source code that has been optimized.
- The FORTRAN or C++ compiler translates the source code into an intermediate language.
- A code generator translates the intermediate code into machine language. The code generator can optimize the final executable code to speed it up, depending on the selected compiler options. You can increase the amount of optimization performed in this step by hand-tuning or preprocessing first.

The speed increase is affected by two factors:

- The amount of optimization applied to individual parts of the program
- The frequency of use for those parts of the program at run time

Speeding up a single routine might speed up the program significantly if that routine performs the majority of the work, on the other hand, it might not improve overall performance much if the routine is rarely called and does not take long anyway. Keep this point in mind when evaluating the performance techniques and data, so that you focus on the techniques that are most valuable in your work.

This chapter contains the following major sections:

- Profiling
- Compiler Optimization Techniques
- Optimizing Preprocessors for FORTRAN and C
- Code-Optimization Techniques

Profiling

You can use profiling tools to identify which portions of the program are executed most frequently or where most of the time is spent. Profilers are typically used after a basic tool, such as the **vmstat** or **iostat** commands, shows that a CPU bottleneck is causing the slow performance.

Before you begin locating hot spots in your program, you need a fully functional program and realistic data values to feed it to.

Timing Commands

Use the timing commands discussed in *Using the time Command to Measure CPU Use for testing and debugging programs whose performance you are recoding and trying to improve*. The output from the **time** command is in minutes and seconds, as follows:

```
real    0m26.72s
user    0m26.53s
sys     0m0.03s
```

The output from the **timex** command is in seconds:

```
real 26.70
user 26.55
sys  0.02
```

Comparing the user+sys CPU time to the real time will give you an idea if your application is CPU-bound or I/O-bound.

Note: Be careful when you do this on an SMP system (see time and timex Cautions).

The **timex** command is also available through the SMIT command on the Analysis Tools menu, found under Performance and Resource Scheduling. The **-p** and **-s** options of the **timex** command allow data from accounting (**-p**) and the sar command (**-s**) to be accessed and reported. The **-o** option reports on blocks read or written.

The prof Command

The **prof** command displays a profile of CPU usage for each external symbol (routine) of a specified program. In detail, it displays the following:

- The percentage of execution time spent between the address of that symbol and the address of the next
- The number of times that function was called
- The average number of milliseconds per call

The **prof** command interprets the profile data collected by the **monitor()** subroutine for the object file (**a.out** by default), reads the symbol table in the object file, and correlates it with the profile file (**mon.out** by default) generated by the **monitor()** subroutine. A usage report is sent to the terminal, or can be redirected to a file.

To use the **prof** command, use the **-p** option to compile a source program in C, FORTRAN, PASCAL, or COBOL. This inserts a special profiling startup function into the object file that calls the **monitor()** subroutine to track function calls. When the program is executed, the **monitor()** subroutine creates a **mon.out** file to track execution time. Therefore, only programs that explicitly exit or return from the main program cause the **mon.out** file to be produced. Also, the **-p** flag causes the compiler to insert a call to the **mcount()** subroutine into the object code generated for each recompiled function of your program. While the program runs, each time a parent calls a child function, the child calls the **mcount()** subroutine to increment a distinct counter for that parent-child pair. This counts the number of calls to a function.

Note: You cannot use the **prof** command for profiling optimized code.

By default, the displayed report is sorted by decreasing percentage of CPU time. This is the same as when specifying the **-t** option.

The **-c** option sorts by decreasing number of calls and the **-n** option sorts alphabetically by symbol name.

If the **-s** option is used, a summary file **mon.sum** is produced. This is useful when more than one profile file is specified with the **-m** option (the **-m** option specifies files containing monitor data).

The **-z** option includes all symbols, even if there are zero calls and time associated.

Other options are available and explained in the **prof** command in the *AIX 5L Version 5.1 Commands Reference*.

The following example shows the first part of the **prof** command output for a modified version of the Whetstone benchmark (Double Precision) program.

```

# cc -o cwhet -p -lm cwhet.c
# cwhet > cwhet.out
# prof
Name           %Time   Seconds   Cumsecs  #Calls  msec/call
.main          32.6    17.63     17.63    1       17630.
.__mcount      28.2    15.25     32.88
.mod8          16.3    8.82      41.70   8990000  0.0010
.mod9          9.9     5.38      47.08   6160000  0.0009
.cos           2.9     1.57      48.65   1920000  0.0008
.exp           2.4     1.32      49.97   930000   0.0014
.log           2.4     1.31      51.28   930000   0.0014
.mod3          1.9     1.01      52.29   140000   0.0072
.sin           1.2     0.63      52.92   640000   0.0010
.sqrt          1.1     0.59      53.51
.atan          1.1     0.57      54.08   640000   0.0009
.pout          0.0     0.00      54.08    10       0.0
.exit          0.0     0.00      54.08    1       0.
.free          0.0     0.00      54.08    2       0.
.free_y        0.0     0.00      54.08    2       0.

```

In this example, we see many calls to the **mod8()** and **mod9()** routines. As a starting point, examine the source code to see why they are used so much. Another starting point could be to investigate why a routine requires so much time.

Note: If the program you want to monitor uses a **fork()** system call, be aware that the parent and the child create the same file (**mon.out**). To avoid this problem, change the current directory of the child process.

The gprof Command

The **gprof** command produces an execution profile of C, PASCAL, FORTRAN, or COBOL programs. The statistics of called subroutines are included in the profile of the calling program. The **gprof** command is useful in identifying how a program consumes CPU resources. It is roughly a superset of the **prof** command, giving additional information and providing more visibility to active sections of code.

The gprof Implementation

The source code must be compiled with the **-pg** option. This action links in versions of library routines compiled for profiling and reads the symbol table in the named object file (**a.out** by default), correlating it with the call graph profile file (**gmon.out** by default). This means that the compiler inserts a call to the **mccount()** function into the object code generated for each recompiled function of your program. The **mccount()** function counts each time a parent calls a child function. Also, the **monitor()** function is enabled to estimate the time spent in each routine.

The **gprof** command generates two useful reports:

- The call-graph profile, which shows the routines, in descending order by CPU time, plus their descendants. The profile allows you to understand which parent routines called a particular routine most frequently and which child routines were called by a particular routine most frequently.
- The flat profile of CPU usage, which shows the usage by routine and number of calls, similar to the **prof** output.

Each report section begins with an explanatory part describing the output columns. You can suppress these pages by using the **-b** option.

Use **-s** for summaries and **-z** to display routines with zero usage.

Where the program is executed, statistics are collected in the **gmon.out** file. These statistics include the following:

- The names of the executable program and shared library objects that were loaded
- The virtual memory addresses assigned to each program segment

- The **mcount()** data for each parent-child
- The number of milliseconds accumulated for each program segment

Later, when the **gprof** command is issued, it reads the **a.out** and **gmon.out** files to generate the two reports. The call-graph profile is generated first, followed by the flat profile. It is best to redirect the **gprof** output to a file, because browsing the flat profile first may answer most of your usage questions.

The following example shows the profiling for the **cwhtet** benchmark program. This example is also used in The prof Command:

```
# cc -o cwhtet -pg -lm cwhtet.c
# cwhtet > cwhtet.out
# gprof cwhtet > cwhtet.gprof
```

Call-Graph Profile: The call-graph profile is the first part of the **cwhtet.gprof** file and looks similar to the following:

granularity: each sample hit covers 4 byte(s) Time: 62.85 seconds

index	%time	self	descendents	called/total called+self called/total	parents name children	index
		19.44	21.18	1/1	._start	[2]
[1]	64.6	19.44	21.18	1	.main	[1]
		8.89	0.00	8990000/8990000	.mod8	[4]
		5.64	0.00	6160000/6160000	.mod9	[5]
		1.58	0.00	930000/930000	.exp	[6]
		1.53	0.00	1920000/1920000	.cos	[7]
		1.37	0.00	930000/930000	.log	[8]
		1.02	0.00	140000/140000	.mod3	[10]
		0.63	0.00	640000/640000	.atan	[12]
		0.52	0.00	640000/640000	.sin	[14]
		0.00	0.00	10/10	.pout	[27]

					<spontaneous>	
[2]	64.6	0.00	40.62		._start	[2]
		19.44	21.18	1/1	.main	[1]
		0.00	0.00	1/1	.exit	[37]

Usually the call graph report begins with a description of each column of the report, but it has been deleted in this example. The column headings vary according to type of function (current, parent of current, or child of current function). The current function is indicated by an index in brackets at the beginning of the line. Functions are listed in decreasing order of CPU time used.

To read this report, look at the first index [1] in the left-hand column. The **.main** function is the current function. It was started by **._start** (the parent function is on top of the current function), and it, in turn, calls **.mod8** and **.mod9** (the child functions are beneath the current function). All the accumulated time of **.main** is propagated to **._start**. The **self** and **descendents** columns of the children of the current function add up to the **descendents** entry for the current function. The current function can have more than one parent. Execution time is allocated to the parent functions based on the number of times they are called.

Flat Profile: The flat profile sample is the second part of the **cwhtet.gprof** file and looks similar to the following:

granularity: each sample hit covers 4 byte(s) Total time: 62.85 seconds

% time	cumulative seconds	self seconds	calls	self ms/call	total ms/call	name
30.9	19.44	19.44	1	19440.00	40620.00	.main [1]
30.5	38.61	19.17				._mcount [3]
14.1	47.50	8.89	8990000	0.00	0.00	.mod8 [4]

9.0	53.14	5.64	6160000	0.00	0.00	.mod9 [5]
2.5	54.72	1.58	930000	0.00	0.00	.exp [6]
2.4	56.25	1.53	1920000	0.00	0.00	.cos [7]
2.2	57.62	1.37	930000	0.00	0.00	.log [8]
2.0	58.88	1.26				.qincrement [9]
1.6	59.90	1.02	140000	0.01	0.01	.mod3 [10]
1.2	60.68	0.78				.__stack_pointer [11]
1.0	61.31	0.63	640000	0.00	0.00	.atan [12]
0.9	61.89	0.58				.qincrement1 [13]
0.8	62.41	0.52	640000	0.00	0.00	.sin [14]
0.7	62.85	0.44				.sqrt [15]
0.0	62.85	0.00	180	0.00	0.00	.fwrite [16]
0.0	62.85	0.00	180	0.00	0.00	.memchr [17]
0.0	62.85	0.00	90	0.00	0.00	.__flsbuf [18]
0.0	62.85	0.00	90	0.00	0.00	._flsbuf [19]

The flat profile is much less complex than the call-graph profile and very similar to the output of the **prof** command. The primary columns of interest are the `self seconds` and the `calls` columns. These reflect the CPU seconds spent in each function and the number of times each function was called. The next columns to look at are `self ms/call` (CPU time used by the body of the function itself) and `total ms/call` (time in the body of the function plus any descendent functions called).

Normally, the top functions on the list are candidates for optimization, but you should also consider how many calls are made to the function. Sometimes it can be easier to make slight improvements to a frequently called function than to make extensive changes to a piece of code that is called once.

A cross reference index is the last item produced and looks similar to the following:

Index by function name

[18] .__flsbuf	[37] .exit	[5] .mod9
[34] .__ioctl	[6] .exp	[43] .moncontrol
[20] .__mcount	[39] .expand_catname	[44] .monitor
[3] .__mcount	[32] .free	[22] .myecvt
[23] .__nl_langinfo_std	[33] .free_y	[28] .nl_langinfo
[11] .__stack_pointer	[16] .fwrite	[27] .put
[24] ._doprnt	[40] .getenv	[29] .printf
[35] ._findbuf	[41] .ioctl	[9] .qincrement
[19] ._flsbuf	[42] .isatty	[13] .qincrement1
[36] ._wrtchk	[8] .log	[45] .saved_category_nam
[25] ._xflsbuf	[1] .main	[46] .setlocale
[26] ._xwrite	[17] .memchr	[14] .sin
[12] .atan	[21] .mf2x2	[31] .splay
[38] .catopen	[10] .mod3	[15] .sqrt

[7] .cos [4] .mod8 [30] .write

Note: If the program you want to monitor uses a **fork()** system call, be aware that the parent and the child create the same file (**gmon.out**). To avoid this problem, change the current directory of the child process.

The tprof Command

Standard UNIX performance tools often do not capture enough information to fully describe the enhanced performance and function of the operating system. The **tprof** command is a versatile profiler that provides a detailed profile of CPU usage by every process ID and name. It further profiles at the application level, routine level, and even to the source statement level and provides both a global view and a detailed view. In addition, the **tprof** command can profile kernel extensions, stripped executable programs, and stripped libraries. It will do subroutine level profiling for most executable program on which the **stripnm** command will produce a symbol table.

Because activity is recorded at 100 samples per second, estimates for short-running programs might not be sufficiently accurate. Averaging multiple runs help generate a more accurate picture. The **tprof** command profiles only CPU activity; it does not profile other system resources, such as memory or disks.

The **tprof** command uses the system trace facility. Only one user at a time can execute the trace facility. Therefore, only one **tprof** command can be executing at one time.

Note that the **tprof** command cannot determine the address of a routine when interrupts are disabled. Therefore, it charges any ticks that occur while interrupts are disabled to the **unlock_enable()** routines.

The **tprof** command is described in detail in Using the tprof Program to Analyze Programs for CPU Use. The remainder of this section discusses its importance for application tuning.

Source Level Profiling with tprof

Unless profiling is desired at the source statement level, the **tprof** command requires no recompiling. If source level is desired, compile the C or FORTRAN source with the **-g** option.

The **tprof** command output is placed in a file called `__prog.all` (where *prog* is the name of the program profiled). If source-level profiling is indicated, additional files are created and placed in the current working directory, as follows:

- `__t.subroutine_prog.c` is the profiled source listing for each routine. The file shows each source line, line numbers and tick counts in order by line number.
- `__h.prog.c` is the list of *hottest* source lines in the source file. The order is by tick count. This makes it easy to find hot spots in the program.

The following figure illustrates source-level profiling in a flowchart:

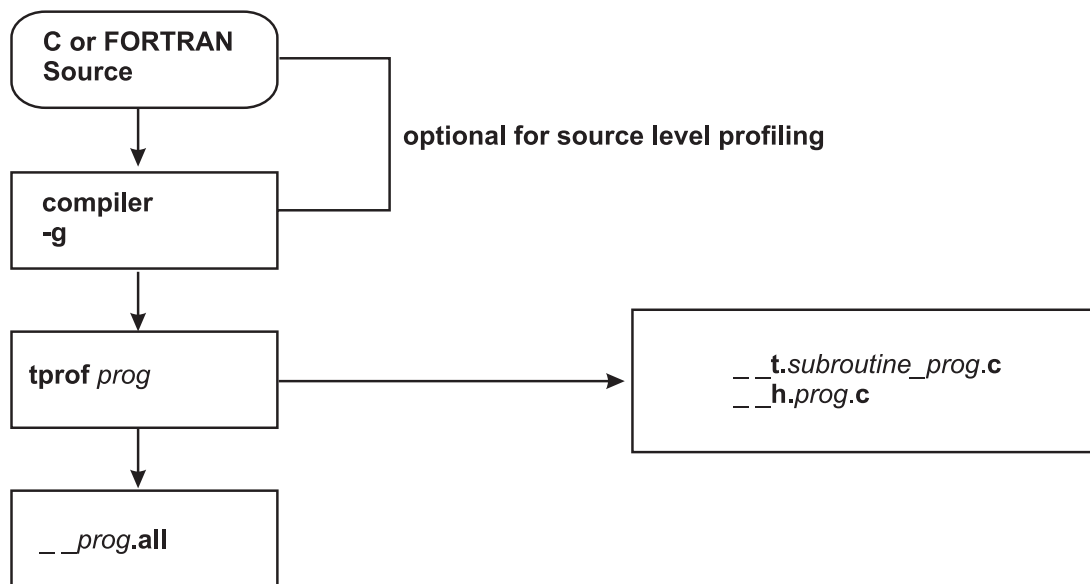

Figure 32. Source Level Profiling. This illustration is a flowchart beginning with a box labeled C or FORTRAN Source. The data path goes down to a second box labeled compiler -g. The path continues down to the next box labeled tprof prog. From here the path can go 2 directions. It can go to the last box labeled __prog.all, or a side box labeled __t.subroutine_prog.c and __h.prog.c. The first 2 boxes are optional for source level profiling.

Reports That the tprof Command Generates

When the **tprof** command is used, one report is always produced: a summary report with the **.all** suffix. This first section contains an estimate of CPU time spent in each process while the program or command was executing. The report shows CPU time, as well as the amount of idle and kernel time.

The second section in the `.all` file summarizes the first section by process. The third section in the `.all` file shows the detail at the subprogram level.

The following figure illustrates the most important files generated and their contents:

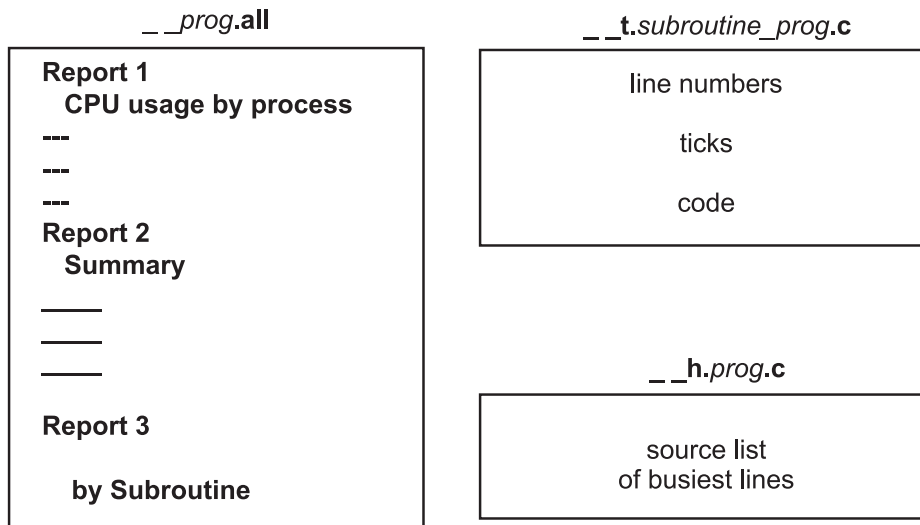

Figure 33. *tprof* Reports. This illustration depicts files generated by the *tprof* command. The first file is `__prog.all` and it contains 3 reports. Report 1 lists CPU usage by process. Report 2 is a summary. Report 3 reports use by subroutine. The next file is the `__t.subroutine_prog.c` file. This file contains line numbers, ticks, and code. The last file is the `__h.prog.c` file. This file contains a source list of the busiest lines.

For an example of the **tprof** command output, see A *tprof* Example.

Compiler Optimization Techniques

The three main areas of source-code tuning are as follows:

- Programming techniques that take advantage of the optimizing compilers and the system architecture.
- BLAS, a library of Basic Linear Algebra Subroutines. If you have a numerically intensive program, these subroutines can provide considerable performance enhancement. An extension of BLAS is ESSL, the Engineering Scientific Subroutine Library. In addition to a subset of the BLAS library, ESSL includes other high-performance mathematical routines for chemistry, engineering, and physics. A Parallel ESSL (PESSL) exists for SMP machines.
- Compiler options and the use of preprocessors like KAP and VAST, available from third-party vendors.

In addition to these source-code tuning techniques, the **fdpr** program restructures object code. The **fdpr** program is described in Restructuring Executable Programs with the *fdpr* Program.

Compiling with Optimization (-O, -O2, -O3, -qstrict, -qhot, -qipa)

To produce a program that achieves good performance, the first step is to take advantage of the basic optimization features built into the compiler. Doing so can increase the speedup that comes from tuning your program and can remove the need to perform some kinds of tuning.

Recommendations

Follow these guidelines for optimization:

- Use **-O2** or **-O3 -qstrict** for any production-level FORTRAN, C, or C++ program you compile. For High Performance FORTRAN (HPF) programs, do not use the **-qstrict** option.
- Use the **-qhot** option for programs where the hotspots are loops or array language. Always use the **-qhot** option for HPF programs.

- Use the **-qipa** option near the end of the development cycle if compilation time is not a major consideration.

The **-qipa** option activates or customizes a class of optimizations known as *interprocedural analysis*. The **-qipa** option has several suboptions that are detailed in the compiler manual. It can be used in two ways:

- The first method is to compile with the **-qipa** option during both the compile and link steps. During compilation, the compiler stores interprocedural analysis information in the **.o** file. During linking, the **-qipa** option causes a complete recompilation of the entire application.
- The second method is to compile the program for profiling with the **-p/-pg** option (with or without **-qipa**), and run it on a typical set of data. The resulting data can then be fed into subsequent compilations with **-qipa** so that the compiler concentrates optimization in the seconds of the program that are most frequently used.

You gain the following benefits when you use compiler optimization:

Branch optimization

Rearranges the program code to minimize branching logic and to combine physically separate blocks of code.

Code motion

If variables used in a computation within a loop are not altered within the loop, the calculation can be performed outside of the loop and the results used within the loop.

Common subexpression elimination

In common expressions, the same value is recalculated in a subsequent expression. The duplicate expression can be eliminated by using the previous value.

Constant propagation

Constants used in an expression are combined, and new ones are generated. Some implicit conversions between integers and floating-point types are done.

Dead code elimination

Eliminates code that cannot be reached or where the results are not subsequently used.

Dead store elimination

Eliminates stores when the value stored is never referenced again. For example, if two stores to the same location have no intervening load, the first store is unnecessary and is removed.

Global register allocation

Allocates variables and expressions to available hardware registers using a "graph coloring" algorithm.

Inlining

Replaces function calls with actual program code

Instruction scheduling

Reorders instructions to minimize execution time

Interprocedural analysis

Uncovers relationships across function calls, and eliminates loads, stores, and computations that cannot be eliminated with more straightforward optimizations.

Invariant IF code floating (Unswitching)

Removes invariant branching code from loops to make more opportunity for other optimizations.

Profile driven feedback

Results from sample program execution are used to improve optimization near conditional branches and in frequently executed code sections.

Reassociation

Rearranges the sequence of calculations in an array subscript expression, producing more candidates for common expression elimination.

Store motion

Moves store instructions out of loops.

Strength Reduction

Replaces less efficient instructions with more efficient ones. For example, in array subscripting, an add instruction replaces a multiply instruction.

Value numbering

Involves constant propagation, expression elimination, and folding of several instructions into a single instruction.

When to Compile without Optimization

Do not use the **-O** option for programs that you intend to debug with a symbolic debugger, regardless of whether you use the **-g** option. However, because optimization is so important to HPF programs, use **-O3 -qhot** for them even during debugging.

The optimizer rearranges assembler-language instructions, making it difficult to map individual instructions to a line of source code. If you compile with the **-g** option, this rearrangement may give the appearance that the source-level statements are executed in the wrong order when you use a symbolic debugger.

If your program produces incorrect results when it is compiled with any of the **-O** options, check your program for unintentionally aliased variables in procedure references.

Compiling for Specific Hardware Platforms (-qarch, -qtune)

Systems can use several type of processors. By using the **-qarch** and **-qtune** options, you can optimize programs for the special instructions and particular strengths of these processors.

Recommendations

Follow these guidelines for compiling for specific hardware platforms:

- If your program will be run only on a single system, or on a group of systems with the same processor type, use the **-qarch** option to specify the processor type.
- If your program will be run on systems with different processor types, and you can identify one processor type as the most important, use the appropriate **-qarch** and **-qtune** settings. XL FORTRAN and XL HPF users can use the **xxlf** and **xxlhp** commands to select these settings interactively.
- If your program is intended to run on the full range of processor implementations, and is not intended primarily for one processor type, do not use either **-qarch** or **-qtune**.

Compiling for Floating-Point Performance (-qfloat)

You can change some default floating-point options to enhance performance of floating-point intensive programs. Some of these options can affect conformance to floating-point standards. Using these options can change the results of computations, but in many cases the result is an increase in accuracy.

Recommendations

Follow these guidelines:

- For single-precision programs on POWER family and POWER2 platforms, you can enhance performance while preserving accuracy by using these floating-point options:

```
-qfloat=fltint:rsqrt:hssngl
```

If your single-precision program is not memory-intensive (for example, if it does not access more data than the available cache space), you can obtain equal or better performance, and greater precision, by using:

```
-qfloat=fltint:rsqrt -qautodbl=dblpad4
```

For programs that do not contain single-precision variables, use **-qfloat=rsqrt:fltint** only. Note that **-O3** without **-qstrict** automatically sets **-qfloat=rsqrt:fltint**.

- Single-precision programs are generally more efficient than double-precision programs on POWER-based systems, so promoting default REAL values to REAL(8) can reduce performance. For POWER-based systems, use the following **-qfloat** suboptions:

```
-qfloat=hssngl:fltint:rsqrt
```

Specifying Cache Sizes (-qcache)

If your program is intended to run exclusively on a single machine or configuration, you can help the compiler tune your program to the memory layout of that machine by using the FORTRAN **-qcache** option. You must also specify the **-qhot** option for **-qcache** to have any effect. The **-qhot** option uses the **-qcache** information to determine appropriate memory-management optimizations.

There are three types of cache: data, instruction, and combined. Models generally fall into two categories: those with both data and instruction caches, and those with a single, combined data/instruction cache. The TYPE suboption lets you identify which type of cache the **-qcache** option refers to.

The **-qcache** option can also be used to identify the size and set associativity of a model's level-2 cache and the Translation Lookaside Buffer (TLB), which is a table used to locate recently referenced pages of memory. In most cases, you do not need to specify the **-qcache** entry for a TLB unless your program uses more than 512 KB of data space.

There may be cases where a lower setting for the SIZE attribute gives enhanced performance, depending on the system load at the time of a run.

Expanding Procedure Calls Inline (-Q)

Inlining involves copying referenced procedures into the code from which they are referenced. This eliminates the calling overhead for inlined routines and enables the optimizer to perform other optimizations in the inlined routines.

For FORTRAN and C programs, you can specify the **-Q** option (along with **-O2** or **-O3**) to have procedures inlined into their reference points.

Inlining enhances performance in some programs, while it degrades performance in others. A program with inlining might slow down because of larger code size, resulting in more cache misses and page faults, or because there are not enough registers to hold all the local variables in some combined routines.

If you use the **-Q** option, always check the performance of the version of your program compiled with **-O3** and **-Q** to that compiled only with **-O3**. Performance of programs compiled with **-Q** might improve dramatically, deteriorate dramatically, or change little or not at all.

The compiler decides whether to inline procedures based on their size. You might be able to enhance your application's performance by using other criteria for inlining. For procedures that are unlikely to be referenced in a typical execution (for example, error-handling and debugging procedures), disable inlining selectively by using the **-Q-names** option. For procedures that are referenced within hot spots, specify the **-Q+names** option to ensure that those procedures are always inlined.

When to Use Dynamic Linking and Static Linking

The operating system provides facilities for creating and using dynamically linked shared libraries. With dynamic linking, external symbols referenced in user code and defined in a shared library are resolved by the loader at load time. When you compile a program that uses shared libraries, they are dynamically linked to your program by default.

The idea behind shared libraries is to have only one copy of commonly used routines and to maintain this common copy in a unique shared-library segment. These common routines can significantly reduce the size of executable programs, thereby saving disk space.

You can reduce the size of your programs by using dynamic linking, but there is usually a tradeoff in performance. The shared library code is not present in the executable image on disk, but is kept in a separate library file. Shared code is loaded into memory once in the shared library segment and shared by all processes that reference it. Dynamically linked libraries therefore reduce the amount of virtual storage used by your program, provided that several concurrently running applications (or copies of the same application) use the procedures provided in the shared library. They also reduce the amount of disk space required for your program provided that several different applications stored on a given system share a library. Other advantages of shared libraries are as follows:

- Load time might be reduced because the shared library code might already be in memory.
- Run-time performance can be enhanced because the operating system is less likely to page out shared library code that is being used by several applications, or copies of an application, rather than code that is only being used by a single application. As a result, fewer page faults occur.
- The routines are not statically bound to the application but are dynamically bound when the application is loaded. This permits applications to automatically inherit changes to the shared libraries, without recompiling or rebinding.

Disadvantages of dynamic linking include the following:

- From a performance viewpoint, there is "glue code" that is required in the executable program to access the shared segment. There is a performance cost in references to shared library routines of about eight machine cycles per reference. Programs that use shared libraries are usually slower than those that use statically-linked libraries.
- A more subtle effect is a reduction in "locality of reference." You may be interested in only a few of the routines in a library, and these routines may be scattered widely in the virtual address space of the library. Thus, the total number of pages you need to touch to access all of your routines is significantly higher than if these routines were all bound directly into your executable program. One impact of this situation is that, if you are the only user of these routines, you experience more page faults to get them all into real memory. In addition, because more pages are touched, there is a greater likelihood of causing an instruction translation lookaside buffer (TLB) miss.
- When a program references a limited number of procedures in a library, each page of the library that contains a referenced procedure must be individually paged into real memory. If the procedures are small enough that using static linking might have linked several procedures that are in different library pages into a single page, then dynamic linking may increase paging thus decreasing performance.
- Dynamically linked programs are dependent on having a compatible library. If a library is changed (for example, a new compiler release may change a library), applications might have to be reworked to be made compatible with the new version of the library. If a library is removed from the system, programs using that library will no longer work.

In statically-linked programs, all code is contained in a single executable module. Library references are more efficient because the library procedures are statically linked into the program. Static linking increases the file size of your program, and it may increase the code size in memory if other applications, or other copies of your application, are running on the system.

The **cc** command defaults to the shared-library option. To override the default, when you compile your programs to create statically-linked object files, use the **-bnso** option as follows:

```
cc xxx.c -o xxx.noshr -0 -bnso -bI:/lib/syscalls.exp
```

This option forces the linker to place the library procedures your program references into the program's object file. The **/lib/syscalls.exp** file contains the names of system routines that must be imported to your program from the system. This file must be specified for static linking. The routines that it names are imported automatically by **libc.a** for dynamic linking, so you do not need to specify this file during dynamic linking. For further details on these options, see Appendix B. Efficient Use of the **ld** Command and the **ld** command.

Determining If Nonshared Libraries Help Performance

One method of determining whether your application is sensitive to the shared-library approach is to recompile your executable program using the `nonshare` option. If the performance is significantly better, you may want to consider trading off the other advantages of shared libraries for the performance gain. Be sure to measure performance in an authentic environment, however. A program that had been bound nonshared might run faster as a single instance in a lightly loaded machine. That same program, when used by a number of users simultaneously, might increase real memory usage enough to slow down the whole workload.

Specifying the Link Order to Reduce Paging for Large Programs

During the linkage phase of program compilation, the linker relocates program units in an attempt to improve locality of reference. For example, if a procedure references another procedure, the linker may make the procedures adjacent in the load module, so that both procedures fit into the same page of virtual memory. This can reduce paging overhead. When the first procedure is referenced for the first time and the page containing it is brought into real memory, the second procedure is ready for use without additional paging overhead.

In very large programs where paging occurs excessively for pages of your program's code, you may decide to impose a particular link order on the linker. You can do this by arranging control sections in the order you want them linked, and by using the `-bnoobjreorder` option to prevent the linker from reordering. A control section or CSECT is the smallest replaceable unit of code or data in an XCOFF object module. For further details, see the *AIX 5L Version 5.1 Files Reference*.

However, there are a number of risks involved in specifying a link order. Any link reordering should always be followed by thorough performance testing to demonstrate that your link order gives superior results for your program over the link order that the linker chooses. Take the following points into account before you decide to establish your own link order:

- You must determine the link order for all CSECTs in your program. The CSECTs must be presented to the linker in the order in which you want to link them. In a large program, such an ordering effort is considerable and prone to errors.
- A performance benefit observed during development of a program can become a performance loss later on, because the changing code size can cause CSECTs that were previously located together in a page to be split into separate pages.
- Reordering can change the frequency of instruction cache-line collisions. On implementations with an instruction cache or combined data and instruction cache that is two-way set-associative, any line of program code can only be stored in one of two lines of the cache. If three or more short, interdependent procedures have the same cache-congruence class, instruction-cache thrashing can reduce performance. Reordering can cause cache-line collisions where none occurred before. It can also eliminate cache-line collisions that occur when `-bnoobjreorder` is not specified.

If you attempt to tune the link order of your programs, always test performance on a system where total real storage and memory utilization by other programs are similar to the anticipated working environment. A link order that works on a quiet system with few tasks running can cause page thrashing on a busier system.

Calling the BLAS and ESSL Libraries

The Basic Linear Algebra Subroutines (BLAS) provide a high level of performance for linear algebraic equations in matrix-matrix, matrix-vector, and vector-vector operations. The Engineering and Scientific Subroutine Library (ESSL), contains a more comprehensive set of subroutines, all of which are tuned for the POWER family, POWER2, and PowerPC architecture. The BLAS and ESSL subroutines can save you considerable effort in tuning many arithmetic operations, and still provide performance that is often better than that obtained by hand-tuning or by automatic optimization of hand-coded arithmetic operations. You can call functions from both libraries from FORTRAN, C, and C++ programs.

The BLAS library is a collection of Basic Linear Algebra Subroutines that have been highly tuned for the underlying architecture. The BLAS subset is provided with the operating system (**/lib/libblas.a**).

Users should use this library for their matrix and vector operations, because they are tuned to a degree that users are unlikely to achieve on their own.

The BLAS routines are designed to be called from FORTRAN programs, but can be used with C programs. Care must be taken due to the language difference when referencing matrixes. For example, FORTRAN stores arrays in column major order, while C uses row major order.

To include the BLAS library, which exists in **/lib/libblas.a**, use the **-lblas** option on the compiler statement (**xlf -O prog.f -lblas**). If calling BLAS from a C program, also include the **-lxlf** option for the FORTRAN library (**cc -O prog.c -lblas -lxlf**).

ESSL is a more advanced library that includes a variety of mathematical functions used in the areas of engineering, chemistry and physics.

Advantages to using the BLAS or ESSL subroutines are as follows:

- BLAS and ESSL subroutine calls are easier to code than the operations they replace.
- BLAS and ESSL subroutines are portable across different platforms. The subroutine names and calling sequences are standardized.
- BLAS code is likely to perform well on all platforms. The internal coding of the routines is usually platform-specific so that the code is closely tied to the architecture's performance characteristics.

In an example program, the following nine lines of FORTRAN code:

```
do i=1,control
do j=1,control
    xmult=0.d0
    do k=1,control
        xmult=xmult+a(i,k)*a(k,j)
    end do
    b(i,j)=xmult
end do
end do
```

were replaced by the following line of FORTRAN that calls a BLAS routine:

```
call dgemm ('n','n',control,control,control,1,d0,a, control,a,1control,1.d0,b,control)
```

The following performance enhancement was observed:

Array Dimension	MULT Elapsed	BLAS Elapsed	Ratio
101 x 101	.1200	.0500	2.40
201 x 201	.8900	.3700	2.41
301 x 301	16.4400	1.2300	13.37
401 x 401	65.3500	2.8700	22.77
501 x 501	170.4700	5.4100	31.51

This example demonstrates how a program using matrix multiplication operations could better use a level 3 BLAS routine for enhanced performance. Note that the improvement increases as the array size increases.

Profile Directed Feedback (PDF)

PDF is a compiler option to do further procedural level optimization such as directing register allocations, instruction scheduling, and basic block rearrangement. To use PDF, do the following:

1. Compile the source files in a program with **-qpdf1** (the function **main()** must be compiled also). The **-lpdf** option is required during the link step. All the other compilation options used must also be used during step 3.
2. Run the program all the way through a typical data set. The program records profiling information when it exits into a file called **__BLOCKS** in the directory specified by the **PDFDIR** environment variable or in the current working directory if that variable is not set. You can run the program multiple times with different data sets, and the profiling information is accumulated to provide an accurate count of how often branches are taken and blocks of code are executed. It is important to use data that is representative of the data used during a typical run of your finished program.
3. Recompile the program using the same compiler options as in step 1, but change **-qpdf1** to **-qpdf2**. Remember that **-L** and **-I** are linker options, and you can change them at this point; in particular, omit the **-lpdf** option. In this second compilation, the accumulated profiling information is used to fine-tune the optimizations. The resulting program contains no profiling overhead and runs at full speed.

Two commands are available for managing the **PDFDIR** directory:

resetpdf *pathname*

Clears all profiling information (but does not remove the data files) from the *pathname* directory. If *pathname* is not specified, from the **PDFDIR** directory; or if **PDFDIR** is not set, from the current directory. When you make changes to the application and recompile some files, the profiling information for these files is automatically reset. Run the **resetpdf** command to reset the profiling information for the entire application, after making significant changes that may affect execution counts for parts of the program that were not recompiled.

cleanpdf *pathname*

Removes all profiling information from the *pathname* or **PDFDIR** or current directory. Removing the profile information reduces the run-time overhead if you change the program and then go through the PDF process again. Run this program after compiling with **-qpdf2**.

The fdpr Command

The **fdpr** command can rearrange the code within a compiled executable program to improve branching performance, move rarely used code away from program hot spots, and do other global optimizations. It works best for large programs with many conditional tests, or highly structured programs with multiple, sparsely placed procedures. The **fdpr** command is described in Restructuring Executable Programs with the fdpr Program.

Optimizing Preprocessors for FORTRAN and C

The KAP and VAST preprocessors for the FORTRAN compiler can restructure FORTRAN source code to better use the POWER family, POWER2, and PowerPC processing unit resources and memory hierarchy. A version of the KAP preprocessor is also available for restructuring the code of C programs. The preprocessors perform memory management optimizations, algebraic transformations, inlining, interprocedural analysis, and other optimizations that improve the performance of FORTRAN or C applications.

Performance tests indicate improvements in the range of 8 to 18 percent, on average, when a suite of programs is compiled with the preprocessors, compared to compiling with the same optimization options for the unpreprocessed version.

The KAP and VAST preprocessors attempt to transform source-level algorithms into algorithms that can take full advantage of the optimizing capabilities of the compiler. The preprocessors also generate listings

that identify the transformations performed and areas of your code that prevent transformations from being carried out. The preprocessors analyze source code, and perform transformations that can improve a program's performance.

Any transformation done by the preprocessors can also be accomplished through hand-tuning. The advantages of using a preprocessor rather than hand-tuning are as follows:

- In many cases, the preprocessors yield programs that perform as efficiently as, or more efficiently than, their hand-tuned equivalents, without a significant investment of programmer time. If you use the preprocessors, you may not require as thorough an understanding of the architecture or of tuning techniques discussed elsewhere in this book.
- For certain programs, you can get code that is highly optimized, simply by selecting appropriate command-line preprocessor options and by adding a small number of directives to the source code of your program. In cases where the preprocessors do not yield a noticeable improvement, work with the preprocessor listings to see what areas of the source code prevent optimization.
- Some of the transformations done by the preprocessors involve considerable expansion of source code. While these expansions can improve your program's efficiency, implementing them through hand-tuning would increase the likelihood of algorithmic and typographical errors, reduce the readability of the source code, and make program maintenance more difficult.
- The preprocessors can generate code that is tuned for a particular architectural configuration, even one that is not available on POWER family, POWER2, and PowerPC systems. You can maintain a single version of source code, and produce transformed versions that are tuned for different POWER, POWER2, and PowerPC models or for machines with other cache and processor characteristics.
- The preprocessors can often improve on hand-tuned code. Although it is possible to tune your programs by hand to as great a level of efficiency as the preprocessors do, some of the more complicated transformations can lead to coding errors when attempted by hand.

Code-Optimization Techniques

The degradation from inefficient use of memory is much greater than that from inefficient use of the caches, because the difference in speed between memory and disk is much higher than between cache and memory. Code-optimization techniques include the following:

- To minimize the code working set of a program, pack frequently executed code together, while separating infrequently used code. In other words, do not put long blocks of error handling code in line and load frequently called modules next to their callers.
- To minimize the data working set, concentrate frequently used data together and avoid unnecessary references to pages. This can be accomplished by using the **malloc()** subroutine instead of the **calloc()** subroutine, initializing data structures immediately before they are used and being sure to free and disclaim allocated space when no longer needed.
- To minimize pinned storage, package pinned code in separate load modules. Make sure it is necessary to use pinned code. Certain system structures (such as mbuf pools) are pinned in memory; do not arbitrarily increase them.
- Real-time techniques can be used, such as the **plock()** subroutine to pin code in memory, and priorities pinned with the **setpri()** subroutine.

Mapped Files

The use of mapped files is another code-optimization technique. Applications can use the **shmat()** or **mmap()** system calls to access files by address, instead of using multiple read and write system calls. Because there is always overhead associated with system calls, the fewer calls used, the better. The **shmat()** or **mmap()** calls can enhance performance up to 50 times compared with traditional **read()** or **write()** system calls. To use the **shmat()** subroutine, a file is opened and a file descriptor (*fd*) returned, just as if read or write system calls are being used. A **shmat()** call then returns the address of the mapped file. Setting elements equal to subsequent addresses in a file, instead of using multiple read system calls, does read from a file to a matrix.

The **mmap()** call allows mapping of memory to cross segment boundaries. A user can have more than 10 areas mapped into memory. The **mmap()** functions provide page-level protection for areas of memory. Individual pages can have their own read or write, or they can have no-access permissions set. The **mmap()** call allows the mapping of only one page of a file.

The **shmat()** call also allows mapping of more than one segment, when a file being mapped is greater than a segment.

The following example program reads from a file using read statements:

```
fd = open("myfile", O_RDONLY);
for (i=0; i<cols; i++) {
    for (j=0; j<rows; j++) {
        read(fd, &n, sizeof(char));
        *p++ = n;
    }
}
```

Using the **shmat()** subroutine, the same result is accomplished without read statements:

```
fd = open("myfile", O_RDONLY);
nptr = (signed char *) shmat(fd, 0, SHM_MAP | SHM_RDONLY);
for (i=0; i<cols; i++) {
    for (j=0; j<rows; j++) {
        *p++ = *nptr++;
    }
}
```

The only drawback to using explicitly mapped files is on the writes. The system write-behind feature, that periodically writes modified pages to a file in an orderly fashion using sequential blocks, does not apply when an application uses the **shmat()** or **mmap()** subroutine. Modified pages can collect in memory and will only be written randomly when the Virtual Memory Manager (VMM) needs the space. This situation often results in many small writes to the disk, causing inefficiencies in CPU and disk usage.

Appendix A. Monitoring and Tuning Commands and Subroutines

Performance tools for the system environment fall into two general categories: those that tell you what is occurring and those that let you do something about it. A few tools do both. This appendix lists these performance-related commands and subroutines. For details of the syntax and functions of the commands, see the *AIX 5L Version 5.1 Commands Reference*.

Some of the performance-related commands are packaged as part of the **perfagent.tools** fileset that is shipped with the Base Operating System. You can determine whether the PTX tools have been installed by running the following command:

```
# ls1pp -lI perfagent.tools
```

If this package is listed as COMMITTED, the PTX tools can be used.

This appendix contains the following major sections:

- Performance Reporting and Analysis Commands
- Performance Tuning Commands
- Performance-Related Subroutines

Performance Reporting and Analysis Commands

Performance reporting and analysis commands give you information on the performance of one or more aspects of the system, or on one or more of the parameters that affect performance. The commands are as follows:

Command

Function

alstat Reports alignment exceptions counts

atmstat

Shows Asynchronous Transfer Mode (ATM) adapter statistics

emstat

Reports emulation instruction counts

entstat

Shows ethernet device driver and device statistics

fddistat

Shows FDDI device driver and device statistics

filemon

Uses the trace facility to report on the I/O activity of physical volumes, logical volumes, individual files, and the Virtual Memory Manager

fileplace

Displays the physical or logical placement of the blocks that constitute a file within the physical or logical volume on which they reside

gprof Reports the flow of control among the subroutines of a program and the amount of CPU time consumed by each subroutine

ifconfig

Configures or displays network interface parameters for a network using TCP/IP

iostat Displays utilization data for:

- Terminals

- CPU
- Disks
- Adapters (AIX 5.1 and subsequent releases)

ipfilter

Extracts different operation headers from an **ipreport** output file and displays them in a table

ipreport

Generates a packet trace report from the specified packet trace file

iptrace

Provides interface-level packet tracing for Internet protocols

lockstat

Displays information about kernel lock contention (only available in AIX Version 4)

locktrace

Turns on lock tracing (only available in AIX 5.1 and subsequent releases)

lsattr Displays attributes of the system that affect performance, such as:

- Processor speed (AIX 5.1 and subsequent releases)
- Size of the caches
- Size of real memory
- Maximum number of pages in the block I/O buffer cache
- Maximum number of kilobytes of memory allowed for mbufs
- High- and low-water marks for disk-I/O pacing

lsdev Displays devices in the system and their characteristics

lslv Displays information about a logical volume

lspas Displays the characteristics of paging spaces

lspv Displays information about a physical volume within a volume group

lsvg Displays information about volume groups

netpmon

Uses the trace facility to report on network activity, including:

- CPU consumption
- Data rates
- Response time

netstat

Displays a wide variety of configuration information and statistics on communications activity, such as:

- Current status of the mbuf pool
- Routing tables
- Cumulative statistics on network activity

nfsd Displays (or changes) the values of NFS options

nfsstat

Displays statistics on Network File System (NFS) and Remote Procedure Call (RPC) server and client activity

no Displays (or changes) the values of network options, such as:

- Default send and receive socket buffer sizes
- Maximum total amount of memory used in mbuf and cluster pools

pd_t_config

Starts, stops, or changes the parameters of the Performance Diagnostic Tool

pd_t_report

Generates a PDT report based on the current historical data

pprof Reports CPU usage of all kernel threads over a period of time

prof Displays object file profile data

ps Displays statistics and status information about the processes in the system, such as:

- Process ID
- I/O activity
- CPU utilization

sar Displays statistics on operating-system activity, such as:

- Directory accesses
- Read and write system calls
- Forks and execs
- Paging activity

schedtune

Displays (or changes) the values of VMM memory-load-control parameters, the CPU-time-slice duration, and the paging-space-low retry interval

smitty Displays (or changes) system-management parameters

svmon

Reports on the status of memory at system, process, and segment levels

tcpdump

Prints out packet headers

time, timex

Prints the elapsed and CPU time used by the execution of a command

topas Reports selected local system statistics

tokstat

Shows Token-Ring device driver and device statistics

tprof Uses the trace facility to report the CPU consumption of kernel services, library subroutines, application-program modules, and individual lines of source code in the application program

trace, trcrpt

Writes a file that records the exact sequence of activities within the system

traceroute

Prints the route that IP packets take to a network host

vmstat

Displays VMM data, such as:

- Number of processes that are dispatchable or waiting
- Page-frame free-list size
- Page-fault activity
- CPU utilization

vmtune

Displays (or changes) the page-replacement algorithm parameters for the Virtual Memory Manager (VMM)

Performance Tuning Commands

The following tools allow you to change one or more performance-related aspects of the system.

Command

Function

bindprocessor

Binds a process to a processor

chdev Changes the characteristics of a device

chlv Changes only the characteristics of a logical volume

chps Changes attributes of a paging space

fdpr Optimizes executable files for a specific workload

ifconfig

Configures or displays network interface parameters for a network using TCP/IP

migratepv

Moves allocated physical partitions from one physical volume to one or more other physical volumes

mkps Adds an additional paging space to the system

nfso Changes (or displays) the values of NFS options

nice Executes a command at a specified priority

no Changes (or displays) the values of network options

renice Changes the priority of running processes

reorgvg

Reorganizes elements of a volume group

rmss Temporarily reduces the effective RAM size of a system to assess the probable performance of a workload on a smaller machine or to ascertain the memory requirement of one element of a workload

schedtune

Changes (or displays) the values of VMM memory load control parameters, the CPU-time-slice duration, and the paging-space-low retry interval

smitty Changes (or displays) system-management parameters

vmtune

Changes (or displays) the Virtual Memory Manager page-replacement algorithm parameters

Performance-Related Subroutines

The following subroutines can be used in monitoring and tuning performance:

bindprocessor()

Binds kernel threads to a processor

getpri()

Determines the scheduling priority of a running process

getpriority()

Determines the nice value of a running process

getrusage()

Retrieves information about the use of system resources

nice() Increments the nice value of the current process

psdanger()
Retrieves information about paging space use

setpri()
Changes the priority of a running process to a fixed priority

setpriority()
Sets the nice value of a running process

Appendix B. Efficient Use of the `ld` Command

The binder (invoked as the final stage of a compile or directly by the `ld` command) has functions that are not found in the typical UNIX linker. This situation can result in longer linking times if the additional power of the operating system binder is not exploited. This appendix describes some techniques for more efficient use of the binder.

Rebindable Executable Programs

The formal documentation of the binder refers to the ability of the binder to take an executable program (a load module) as input. Exploitation of this function can significantly improve the overall performance of the system with software-development workloads, as well as the response time of individual `ld` commands.

In most typical UNIX systems, the `ld` command always takes as input a set of files containing object code, either from individual `.o` files or from archived libraries of `.o` files. The `ld` command then resolves the external references among these files and writes an executable program with the default name of `a.out`. The `a.out` file can only be executed. If a bug is found in one of the modules that was included in the `a.out` file, the defective source code is changed and recompiled, and then the entire `ld` process must be repeated, starting from the full set of `.o` files.

In this operating system, however, the binder can accept both `.o` and `a.out` files as input, because the binder includes resolved External Symbol Dictionary (ESD) and Relocation Dictionary (RLD) information in the executable file. This means that the user has the ability to rebind an existing executable program to replace a single modified `.o` file, rather than build a new executable program from the beginning. Because the binding process consumes storage and processor cycles partly in proportion to the number of different files being accessed and the number of different references to symbols that have to be resolved, rebinding an executable program with a new version of one module is much quicker than binding it from scratch.

Prebound Subroutine Libraries

Equally important in some environments is the ability to bind an entire subroutine library in advance of its use. The system subroutine libraries such as `libc.a` are, in effect, shipped in binder-output format, rather than as an archive file of `.o` files. This saves the user considerable processing time when binding an application with the required system libraries, because only the references from the application to the library subroutines have to be resolved. References among the system library routines themselves have already been resolved during the system-build process.

Many third-party subroutine libraries, however, are routinely shipped in archive form as raw `.o` files. When users bind applications with such libraries, the binder must resolve symbols for the entire library each time the application is bound. This results in long bind times in environments where applications are being bound with large libraries on small machines.

The performance difference between bound and unbound libraries can be significant, especially in minimum configurations.

Examples

Following is an example that illustrates efficient use of the `ld` command:

1. To prebind a library, use the following command on the archive file:

```
# ld -r libfoo.a -o libfoo.o
```

2. The compile and bind of the FORTRAN program `something.f` is as follows:

```
# xlf something.f libfoo.o
```

Notice that the prebound library is treated as another ordinary input file, not with the usual library identification syntax (**-lfoo**).

3. To recompile the module and rebind the executable program after fixing a bug, use the following:

```
# xlf something.f a.out
```

4. However, if the bug fix had resulted in a call to a different subroutine in the library, the bind would fail. The following Korn shell script tests for a failure return code and recovers:

```
# !/usr/bin/ksh
# Shell script for source file replacement bind
#
xlf something.f a.out
rc=$?
if [ "$rc" != 0 ]
then
echo "New function added ... using libfooa.o"
xlf something.o libfooa.o
fi
```

Appendix C. Accessing the Processor Timer

Attempts to measure very small time intervals are often frustrated by the intermittent background activity that is part of the operating system and by the processing time consumed by the system time routines. One approach to solving this problem is to access the processor timer directly to determine the beginning and ending times of measurement intervals, run the measurements repeatedly, and then filter the results to remove periods when an interrupt intervened.

The POWER and POWER2 architectures implement the processor timer as a pair of special-purpose registers. The POWER-based architecture defines a 64-bit register called the *TimeBase*. Only assembler-language programs can access these registers.

Note: The time measured by the processor timer is the absolute wall-clock time. If an interrupt occurs between accesses to the timer, the calculated duration will include the processing of the interrupt and possibly other processes being dispatched before control is returned to the code being timed. The time from the processor timer is the raw time and should never be used in situations in which it will not be subjected to a reasonableness test.

A pair of library subroutines make access to the TimeBase registers architecture-independent. The subroutines are as follows:

read_real_time()

This subroutine obtains the current time from the appropriate source and stores it as two 32-bit values.

time_base_to_time()

This subroutine ensures that the time values are in seconds and nanoseconds, performing any necessary conversion from the TimeBase format.

The time-acquisition and time-conversion functions are separated in order to minimize the overhead of time acquisition.

The following example shows how these subroutines could be used to measure the elapsed time for a specific piece of code:

```
#include <stdio.h>
#include <sys/time.h>

int main(void) {
    timebasestruct_t start, finish;
    int val = 3;
    int w1, w2;
    double time;

    /* get the time before the operation begins */
    read_real_time(&start, TIMEBASE_SZ);

    /* begin code to be timed */
    printf("This is a sample line %d \n", val);
    /* end code to be timed */

    /* get the time after the operation is complete */
    read_real_time(&finish, TIMEBASE_SZ);

    /* call the conversion routines unconditionally, to ensure
     * that both values are in seconds and nanoseconds regardless
     * of the hardware platform. */
    time_base_to_time(&start, TIMEBASE_SZ);
    time_base_to_time(&finish, TIMEBASE_SZ);

    /* subtract the starting time from the ending time */
```

```

w1 = finish.tb_high - start.tb_high; /* probably zero */
w2 = finish.tb_low - start.tb_low;

/* if there was a carry from low-order to high-order during */
/* the measurement, we may have to undo it. */
if (w2 < 0) {
    w1--;
    w2 += 1000000000;
}

/* convert the net elapsed time to floating point microseconds */
time = ((double) w2)/1000.0;
if (w1 > 0)
    time += ((double) w1)*1000000.0;

printf("Time was %9.3f microseconds \n", time);
exit(0);
}

```

To minimize the overhead of calling and returning from the timer routines, the analyst can experiment with binding the benchmark nonshared (see *When to Use Dynamic Linking and Static Linking*).

If this were a real performance benchmark, we would perform the code to be measured repeatedly. If we timed a number of consecutive repetitions collectively, we could calculate an average time for the operation, but it might include interrupt handling or other extraneous activity. If we timed a number of repetitions individually, we could inspect the individual times for reasonableness, but the overhead of the timing routines would be included in each measurement. It may be desirable to use both techniques and compare the results. In any case, the analyst will want to consider the purpose of the measurements in choosing the method.

POWER-based-Architecture-Unique Timer Access

Note: The following discussion applies only to the POWER and POWER2 architectures (and the 601 processor chip). The code examples will function correctly in a POWER-based system, but some of the instructions will be simulated. Because the purpose of accessing the processor timer is to obtain high-precision times with low overhead, simulation makes the results much less useful.

The POWER and POWER2 processor architectures include two special-purpose registers (an upper register and a lower register) that contain a high-resolution timer. The upper register contains time in seconds, and the lower register contains a count of fractional seconds in nanoseconds. The actual precision of the time in the lower register depends on its update frequency, which is model-specific.

Assembler Routines to Access the POWER Timer Registers

The following assembler-language module (**timer.s**) provides routines (`rtc_upper` and `rtc_lower`) to access the upper and lower registers of the timer:

```

        .globl  .rtc_upper
.rtc_upper: mfspr    3,4          # copy RTCU to return register
            br

        .globl  .rtc_lower
.rtc_lower: mfspr    3,5          # copy RTCL to return register
            br

```

C Subroutine to Supply the Time in Seconds

The following module (**second.c**) contains a C routine that calls the **timer.s** routines to access the upper and lower register contents. It returns a double-precision real value of time in seconds.

```

double second()
{
    int ts, t1, tu;

    ts = rtc_upper();    /* seconds          */
    t1 = rtc_lower();    /* nanoseconds     */
    tu = rtc_upper();    /* Check for a carry from */
    if (ts != tu)        /* the lower reg to the upper. */
        t1 = rtc_lower(); /* Recover from the race condition. */
    return ( tu + (double)t1/1000000000 );
}

```

The subroutine **second()** can be called from either a C routine or a FORTRAN routine.

Note: Depending on the length of time since the last system reset, the **second.c** module might yield a varying amount of precision. The longer the time since reset, the larger the number of bits of precision consumed by the whole-seconds part of the number. The technique shown in the first part of this appendix avoids this problem by performing the subtraction required to obtain an elapsed time before converting to floating point.

Accessing Timer Registers in POWER-based Systems

The POWER-based architecture includes a 64-bit TimeBase register, which is logically divided into 32-bit upper and lower fields (TBU and TBL). The TimeBase register is incremented at a frequency that is hardware- and software-implementation dependent and may vary from time to time. Transforming the values from TimeBase into seconds is a more complex task than in the POWER architecture. To obtain time values in POWER-based systems, use the **read_real_time()** and **time_base_to_time()** interfaces.

Example of the second Subroutine

An example (**main.c**) of a C program using the **second()** subroutine is as follows:

```

#include <stdio.h>
double second();
main()
{
    double t1,t2;

    t1 = second();
    my_favorite_function();
    t2 = second();

    printf("my_favorite_function time: %7.9f\n",t2 - t1);
    exit();
}

```

An example (**main.f**) of a FORTRAN program using the **second()** subroutine is as follows:

```

double precision t1
double precision t2

t1 = second()
my_favorite_subroutine()
t2 = second()
write(6,11) (t2 - t1)
11 format(f20.12)
end

```

To compile and use either **main.c** or **main.f**, use the following:

```

xlc -O3 -c second.c timer.s
xlf -O3 -o mainF main.f second.o timer.o
xlc -O3 -o mainC main.c second.o timer.o

```

Appendix D. Determining CPU Speed

When using AIX 5.1 and subsequent releases, the following code returns the processor speed in hertz (Hz):

```
lsattr -E -l proc0 | grep "Processor Speed"
```

When using earlier releases than AIX 5.1, use the **uname** command. Running the **uname -m** command produces output of the following form:

```
xyyyyyymmss
```

where:

xx 00

yyyyyy
Unique CPU ID

mm Model ID (the numbers to use to determine CPU speed)

ss 00 (Submodel)

By cross-referencing the mm values from the **uname -m** output with the table below, you can determine the processor speed.

Model ID	Machine Type	Processor Speed	Architecture
02	7015-930	25	Power
10	7013-530	25	Power
10	7016-730	25	Power
11	7013-540	30	Power
14	7013-540	30	Power
18	7013-53H	33	Power

Note 1

For systems where the **uname -m** command outputs a model ID of 4C; in general, the only way to determine the processor speed of a machine with a model ID of 4C is to reboot into System Management Services and choose the system configuration options. However, in some cases, the information gained from the **uname -M** command can be helpful, as shown in the following table.

uname -M	Machine Type	Processor Speed	Processor Architecture
IBM,7017-S70	7017-S70	125	RS64
IBM,7017-S7A	7017-S7A	262	RD64-II
IBM,7017-S80	7017-S80	450	RS-III
IBM,7025-F40	7025-F40	166/233	PowerPC
IBM,7025-F50	7025-F50	See Note 4.	PowerPC
IBM,7026-H10	7026-H10	166/233	PowerPC
IBM,7026-H50	7026-H50	See Note 4.	PowerPC
IBM,7026-H70	7026-H70	340	RS64-II
IBM,7042/7043 (ED)	7043-140	166/200/233/332	PowerPC
IBM,7042/7043 (ED)	7043-150	375	PowerPC
IBM,7042/7043 (ED)	7043-240	166/233	PowerPC
IBM,7043-260	7043-260	200	Power3
IBM,7248	7248-100	100	PowerPersonal
IBM,7248	7248-120	120	PowerPersonal
IBM,7248	7248-132	132	PowerPersonal
IBM,9076-270	9076-SP Silver Node	See Note 4.	PowerPC

Note 2:

For J-Series, R-Series, and G-Series systems, you can determine the processor speed in an MCA SMP system from the FRU number of the CPU card by using the following command:

```
# lscfg -v1 cpucard0 | grep FRU
FRU Number      Processor Type      Processor Speed
    E1D          PowerPC 601         75
    C1D          PowerPC 601         75
    C4D          PowerPC 604         112
    E4D          PowerPC 604         112
    X4D          PowerPC 604e        200
```

Note 3:

For the E-series and F-30 systems use the following command to determine CPU speed:

```
# lscfg -vp | pg
```

Look for the following stanza:

```
procF0                      CPU Card

Part Number.....093H5280
EC Level.....00E76527
Serial Number.....17700008
FRU Number.....093H2431
Displayable Message.....CPU Card
Device Specific.(PL).....
Device Specific.(ZA).....PS=166,PB=066,PCI=033,NP=001,CL=02,PBH
                                Z=64467000,PM=2.5,L2=1024
Device Specific.(RM).....10031997 140951 VIC97276
ROS Level and ID.....03071997 135048
```

In the section Device Specific.(ZA), the section PS= is the processor speed expressed in MHz.

Note 4:

For F-50 and H-50 systems and SP Silver Node, the following commands can be used to determine the processor speed of an F-50 system:

```
# lscfg -vp | more
```

Look for the following stanza:

```
Orca M5 CPU:
Part Number.....08L1010
EC Level.....E78405
Serial Number.....L209034579
FRU Number.....93H8945
Manufacture ID.....IBM980
Version.....RS6K
Displayable Message.....OrcaM5 CPU DD1.3
Product Specific.(ZC).....PS=0013c9eb00,PB=0009e4f580,SB=0004f27
                                ac0,NP=02,PF=461,PV=05,KV=01,CL=1
```

In the line containing Product Specific.(ZC), the entry PS= is the processor speed in hexadecimal notation. To convert this to an actual speed, use the following conversions:

```
0009E4F580 = 166 MHz
0013C9EB00 = 332 MHz
```

The value PF= indicates the processor configuration.

```
251 = 1 way 166 MHz
261 = 2 way 166 MHz
451 = 1 way 332 MHz
461 = 2 way 332 MHz
```

Appendix E. National Language Support: Locale versus Speed

National Language Support (NLS) facilitates the use of the operating system in various language environments. Because informed use of NLS is increasingly important in obtaining optimum performance from the system, this appendix contains a brief review of NLS.

NLS allows the operating system to be tailored to the individual user's language and cultural expectations. A *locale* is a specific combination of language and geographic or cultural requirements that is identified by a compound name, such as `en_US` (English as used in the United States). For each supported locale, there is a set of message catalogs, collation value tables, and other information that defines the requirements of that locale. When the operating system is installed, the system administrator can choose what locale information should be installed. Thereafter, the individual users can control the locale of each shell by changing the **LANG** and **LC_ALL** variables.

The one locale that does not conform to the structure just described is the C (or POSIX) locale. The C locale is the system default locale unless the user explicitly chooses another. It is also the locale in which each newly forked process starts. Running in the C locale is the nearest equivalent in the operating system to running in the original, unilingual form of UNIX. There are no C message catalogs. Instead, programs that attempt to get a message from the catalog are given back the default message that is compiled into the program. Some commands, such as the **sort** command, revert to their original, character-set-specific algorithms.

The performance of NLS generally falls into three bands. The C locale is generally the fastest for the execution of commands, followed by the single-byte (Latin alphabet) locales such as `en_US`, with the multibyte locales resulting in the slowest command execution.

Programming Considerations

Historically, the C language has displayed a certain amount of provinciality in its interchangeable use of the words `byte` and `character`. Thus, an array declared `char foo[10]` is an array of 10 bytes. But not all of the languages in the world are written with characters that can be expressed in a single byte. Japanese and Chinese, for example, require two or more bytes to identify a particular graphic to be displayed. Therefore, we distinguish between a `byte`, which is 8 bits of data, and a `character`, which is the amount of information needed to represent a single graphic.

Two characteristics of each locale are the maximum number of bytes required to express a character in that locale and the maximum number of output display positions a single character can occupy. These values can be obtained with the **MB_CUR_MAX** and **MAX_DISP_WIDTH** macros. If both values are 1, the locale is one in which the equivalence of byte and character still holds. If either value is greater than 1, programs that do character-by-character processing, or that keep track of the number of display positions used, must use internationalization functions to do so.

Because the multibyte encodings consist of variable numbers of bytes per character, they cannot be processed as arrays of characters. To allow efficient coding in situations where each character has to receive extensive processing, a fixed-byte-width data type, **wchar_t**, has been defined. A **wchar_t** is wide enough to contain a translated form of any supported character encoding. Programmers can therefore declare arrays of **wchar_t** and process them with (roughly) the same logic they would have used on an array of **char**, using the wide-character analogs of the traditional **libc.a** functions.

Unfortunately, the translation from the multibyte form in which text is entered, stored on disk, or written to the display, to the **wchar_t** form, is computationally quite expensive. It should only be performed in situations in which the processing efficiency of the **wchar_t** form will more than compensate for the cost of translation to and from the **wchar_t** form.

Some Simplifying Rules

It is possible to write a slow, multilingual application program if the programmer is unaware of some constraints on the design of multibyte character sets that allow many programs to run efficiently in a multibyte locale with little use of internationalization functions. For example:

- In all code sets supported by IBM, the character codes 0x00 through 0x3F are unique and encode the ASCII standard characters. Being unique means that these bit combinations never appear as one of the bytes of a multibyte character. Because the null character is part of this set, the **strlen()**, **strcpy()**, and **strcat()** functions work on multibyte as well as single-byte strings. The programmer must remember that the value returned by **strlen()** is the number of bytes in the string, not the number of characters.
- Similarly, the standard string function **strchr(foostr, '/')** works correctly in all locales, because the / (slash) is part of the unique code-point range. In fact, most of the standard delimiters are in the 0x00 to 0x3F range, so most parsing can be accomplished without recourse to internationalization functions or translation to **wchar_t** form.
- Comparisons between strings fall into two classes: equal and unequal. Use the standard **strcmp()** function to perform comparisons. When we write

```
if (strcmp(foostr,"a rose") == 0)
```

we are not looking for "a rose" by any other name; we are looking for that set of bits only. If `foostr` contains "a rosE" no match is found.

- Unequal comparisons occur when we are attempting to arrange strings in the locale-defined collation sequence. In that case, we would use

```
if (strcoll(foostr,barstr) > 0)
```

and pay the performance cost of obtaining the collation information about each character.

- When a program is executed, it always starts in the C locale. If it will use one or more internationalization functions, including accessing message catalogs, it must execute:

```
setlocale(LC_ALL, "");
```

to switch to the locale of its parent process before calling any internationalization function.

Setting the Locale

The following command sequence:

```
LANG=C
export LANG
```

sets the default locale to C (that is, C is used unless a given variable, such as **LC_COLLATE**, is explicitly set to something else).

The following sequence:

```
LC_ALL=C
export LC_ALL
```

forcibly sets all the locale variables to C, regardless of previous settings.

For a report on the current settings of the locale variables, type **locale**.

Appendix F. Performance Tuning with AIX Fast Connect For Windows and OS/2

AIX Fast Connect for Windows allows PC clients running Microsoft networking protocols to access native UNIX file systems and native UNIX printer spool subsystem. AIX Fast Connect for Windows is commonly called a Server Message Block (SMB) server. It runs Network Basic Input/Output System (NetBIOS) over Transmission Control Protocol/Internet Protocol (TCP/IP). AIX Fast Connect offers both file and print services to PC clients running Microsoft Windows 95/98, Windows NT, Windows 2000, Windows for Workgroups, or OS/2.

Features:

- File System Support with Common File Names
- Print Queue Support
- Local Master Browser Support
- WINS Server and Client Support
- Opportunistic Locks
- NT Domain Passthru
- Unicode support
- Command line, SMIT, Web-based System Manager
- Encrypted Passwords
- DCE/DFS File System Support

The options presented here are applicable to versions 2.1.1 and 3.0.0 of AIX Fast Connect for Windows and OS/2.

- Network tuning performance

Review Chapter 9. Monitoring and Tuning Communications I/O Use. The AIX Fast Connect server runs NetBIOS over TCP/IP. Most network-tuning options will apply and be transparent to the SMB server.

- Disk-tuning performance and file system-tuning performance

Review Chapter 8. Monitoring and Tuning Disk I/O Use. The shares you export to PC clients are native file systems, so any and all file system and disk tuning options will apply and be transparent to the SMB server.

See the *AIX 5L Version 5.1 System Management Guide: Communications and Networks* for more information.

Monitoring AIX Fast Connect

The **net** command has arguments to show system information about the AIX Fast Connect for Windows Server subsystem. For details on the **net** command, see the *AIX 5L Version 5.1 Commands Reference*.

The AIX Fast Connect Server also has a full range of system trace hooks that can be used to gain information on the running system. See the **/etc/trcfmt** file for implementation-specific details for the system you are running on.

The following trace hooks are of interest:

- 2EE - CIFS Enter
- 2EF - CIFS Exit
- 2F0 - CIFS-FSS
- 2F1 - CIFS-LOGON

- 2F2 - CIFS-NET
- 2F3 - CIFS-SMB PARSER
- 2F4 - CIFS-PSS
- 2F5 - CIFS-SMS

Tuning AIX Fast Connect

All of the following tuning options were investigated using a freely available file server benchmark called Netbench from ZD, Inc. Printing performance is not discussed in this appendix, nor is any specific capacity-planning information.

- AIX Fast Connect Tuning Options

The suggested method of configuring AIX Fast Connect for Windows is to use installed Web-based System Manager or terminal-based (**smitty smb**) configuration tools. The following options may be used in the `/etc/cifs/cifsConfig` file and have an effect on file server performance. See the *AIX 5L Version 5.1 System Management Guide: Communications and Networks* for more information concerning the options listed below:

accesscheckinglevel (0, 1)

Enables support for a fast-path access-checking subroutine. It assumes that the process has permissions to access all file paths in the system. It avoids a longer RPC based authentication mechanism.

cache_searches (0, 1)

Note: This option is only available in AIX Version 3
This option enables caching of the shared filesystems directories information within the CIFS server. If search caching is needed, this parameter should be enabled as well as the per share directory caching option.

casepreserve (0, 1) and casesensitive (0, 1)

Request the server to preserve case and to recognize uppercase and lowercase during file-name matching operations. You may not be able to simplify the complex searches because of client requirements.

del_inactive_searches (0,1)

When enabled, this option deletes inactive search handles left open by the clients.

dosfilenamemapping (0, 1)

Controls how long file names are mapped to 8.3 format. If enabled, long file names are mapped into the DOS 8.3 format. Disabling DOS file-name mapping is more efficient.

filenamematchinglevel (0, 1)

Enables case-insensitive matching. You may be able to disable this option depending on the client you are using. Disabling case sensitivity matching improves performance. This option is superseded by **casepreserve** and **casesensitive** options.

oplockfiles (no, yes)

Enables opportunistic locking support in the AIX Fast Connect for Windows server. The default is yes and should be enabled for best possible performance. This configuration option can have a very large impact on file-server performance.

send_file_api (0, 1)

Enables support for the sendfile API from the AIX Fast Connect Server for Windows. This option will use the built-in Network Buffer Cache system support. If you turn this option on, test with the Network Buffer Cache enabled to see if your file server traffic benefits from this operating system feature. You might find better performance using the sendfile API without the Network Buffer Cache network option enabled (**nbc_limit = 0**). See the **no** command option for more information on configuring the Network Buffer Cache subsystem.

send_file_cache_size (default 1048576)

Determines the largest read value where the sendfile API will cache the file. Tune this value depending on your own specific environment.

send_file_size (default 4096)

Determines the smallest read size that will use the sendfile API. This is the low-water mark for caching read requests. Tune this value depending on your own specific environment.

statistics (0, 1)

Enables and disables the collection of server statistics that can be viewed using the **net statistics** command. If you set this option to zero, the output from the **net statistics** command will show zero totals. It does not constitute a large amount of overhead.

- Operating System Tuning

The AIX Fast Connect for Windows server runs in the application space and is a threaded application. The AIX Fast Connect for Windows server uses the pthread library. Export the following environment variables from the shell before starting the AIX Fast Connect for Windows server. The best performance is achieved on MP servers by running with the malloc multiheap support and one kernel thread to one runnable pthread.

- **AIXTHREAD_SCOPE=S**
- **AIXTHREAD_MNRATIO=1:1**
- **MALLOCMULTIHEAP=1**

You can also disable debugging in **libpthreads.a** before you start the **cifsServer** program.

- **AIXTHREAD_RWLOCK_DEBUG=OFF**
- **AIXTHREAD_COND_DEBUG=OFF**
- **AIXTHREAD_MUTEX_DEBUG=OFF**

If you encounter problems debugging applications that use **libpthreads.a**, you can turn the debugging options back on until you have a stable application.

- NetBench Configuration Options

Shown below are suggested configurations changes for the AIX Fast Connect for Windows Server if you want to run with the NetBench benchmarking software. This configuration assumes that you will be running with Microsoft NT v4.0 clients at SP5 or higher. These settings also assume that you have set the AIX Network Buffer Cache (**nbc_limit**) to zero.

Following are suggested changes to the initial default configuration parameters in the **/etc/cifs/cifsConfig** file:

- For Netbench version 6.0:
 - **encrypt_passwords=1**
 - **statistics = 0**
 - **send_file_api = 1**
 - **dosfilenamemapping = 0**
 - **filenamematchinglevel = 1**
 - **casepreserve = 1**
 - **casesensitive = 0**
 - **accesscheckinglevel = 0**
 - **del_inactive_searches=1**
 - **cache_searches=1**

Appendix G. Summary of Tunable Parameters

Each of the following sections describes one of the operating system's parameters that can affect performance. This appendix contains the following major sections:

- Environment Variables
- Kernel Tunable Parameters
- Network Tunable Parameters

The parameters are described in alphabetical order within each section.

Environment Variables

This section discusses the following topics:

- Thread Support Tunable Parameters
- Miscellaneous Tunable Parameters

Thread Support Tunable Parameters

Following is a list of *thread support parameters* that can be tuned:

1. AIXTHREAD_COND_DEBUG (AIX 4.3.3 and subsequent versions)

Purpose: Maintains a list of condition variables for use by the debugger.

Values: **Default:** ON
Range: ON, OFF

Display: **echo \$AIXTHREAD_COND_DEBUG** (this is turned on internally, so the initial default value will not be seen with the **echo** command)

Change: AIXTHREAD_COND_DEBUG={ON|OFF}
export AIXTHREAD_COND_DEBUG
Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **AIXTHREAD_COND_DEBUG={ON/OFF}** command to the **/etc/environment** file.

Diagnosis: Leaving it on makes debugging threaded applications easier, but may impose some overhead.

Tuning: If the program contains a large number of active condition variables and frequently creates and destroys condition variables, this may create higher overhead for maintaining the list of condition variables. Setting the variable to **OFF** will disable the list.

Refer to "Thread Debug Options" on page 49.

2. AIXTHREAD_ENRUSG

Purpose: Enable or disable pthread resource collection.

Values: **Default:** OFF
Range: ON, OFF

Display: **echo \$AIXTHREAD_ENRUSG** (this is turned on internally, so the initial default value will not be seen with the **echo** command)

Change: AIXTHREAD_ENRUSG={ON|OFF}
export AIXTHREAD_ENRUSG
Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **AIXTHREAD_ENRUSG={ON/OFF}** command to the **/etc/environment** file.

Diagnosis: Turning it on allows for resource collection of all pthreads in a process, but will impose some overhead.

Tuning:

Refer to “Thread Environment Variables” on page 47.

3. AIXTHREAD_GUARDPAGES

Purpose:	Controls the number of guard pages to add to the end of the pthread stack.
Values:	Default: 0 Range: A positive integer
Display:	echo \$AIXTHREAD_GUARDPAGES (This is turned on internally, so the initial default value will not be seen with the echo command)
Change:	<code>AIXTHREAD_GUARDPAGES=<i>n</i></code> <code>export AIXTHREAD_GUARDPAGES</code> Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding AIXTHREAD_GUARDPAGES=<i>n</i> command to the /etc/environment file.
Diagnosis:	N/A
Tuning:	N/A

Refer to “Thread Environment Variables” on page 47.

4. AIXTHREAD_MINKTHREADS (AIX 4.3 and later)

Purpose	Controls the the minimum number of kernel threads that should be used.
Values:	Default: 8 Range: A positive integer value
Display:	echo \$AIXTHREAD_MINKTHREADS (this is turned on internally, so the initial default value will not be seen with the echo command)
Change:	AIXTHREAD_MINKTHREADS=<i>n</i> export AIXTHREAD_MINKTHREADS Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding AIXTHREAD_MINKTHREADS =<i>n</i> command to the /etc/environment file.
Diagnosis:	N/A
Tuning:	The library scheduler will not reclaim kernel threads below this figure. A kernel thread may be reclaimed at virtually any point. Generally, a kernel thread is targeted as a result of a pthread terminating.

Refer to: Variables for Process-Wide Contention Scope

5. AIXTHREAD_MNRATIO (AIX 4.3 and later)

Purpose:	Controls the scaling factor of the library. This ratio is used when creating and terminating pthreads.
Values:	Default: 8:1 Range: Two positive values (<i>p:k</i>), where <i>k</i> is the number of kernel threads that should be employed to handle <i>p</i> runnable pthreads
Display:	echo \$AIXTHREAD_MNRATIO (this is turned on internally, so the initial default value will not be seen with the echo command)
Change:	AIXTHREAD_MNRATIO=<i>p:k</i> export AIXTHREAD_MNRATIO Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding AIXTHREAD_MNRATIO=<i>p:k</i> command to the /etc/environment file.
Diagnosis:	N/A

Tuning: May be useful for applications with a very large number of threads. However, always test a ratio of 1:1 because it may provide for better performance.

Refer to: Variables for Process-Wide Contention Scope

6. AIXTHREAD_MUTEX_DEBUG (AIX 4.3.3 and later)

Purpose: Maintains a list of active mutexes for use by the debugger.

Values: Default: ON
Range: ON, OFF

Display: **echo \$AIXTHREAD_MUTEX_DEBUG** (this is turned on internally, so the initial default value will not be seen with the **echo** command)

Change: **AIXTHREAD_MUTEX_DEBUG={ON/OFF}**
export AIXTHREAD_MUTEX_DEBUG
Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **AIXTHREAD_MUTEX_DEBUG={ON/OFF}** command to the **/etc/environment** file.

Diagnosis: Leaving it on makes debugging threaded applications easier, but may impose some overhead.

Tuning: If the program contains a large number of active mutexes and frequently creates and destroys mutexes, this may create higher overhead for maintaining the list of mutexes. Setting the variable to OFF will disable the list.

Refer to: Thread Debug Options

7. AIXTHREAD_RWLOCK_DEBUG (AIX 4.3.3 and later)

Purpose: Maintains a list of read-write locks for use by the debugger.

Values: Default: ON
Range: ON, OFF

Display: **echo \$AIXTHREAD_RWLOCK_DEBUG** (this is turned on internally, so the initial default value will not be seen with the **echo** command)

Change: **AIXTHREAD_RWLOCK_DEBUG={ON/OFF}**
export AIXTHREAD_RWLOCK_DEBUG
Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **AIXTHREAD_RWLOCK_DEBUG={ON/OFF}** command to the **/etc/environment** file.

Diagnosis: Leaving it on makes debugging threaded applications easier, but may impose some overhead.

Tuning: If the program contains a large number of active read-write locks and frequently creates and destroys read-write locks, this may create higher overhead for maintaining the list of read-write locks. Setting the variable to OFF will disable the list.

Refer to: Thread Debug Options

8. AIXTHREAD_SCOPE (AIX 4.3.1 and later)

Purpose: Controls contention scope. P signifies process-based contention scope (M:N). S signifies system-based contention scope (1:1).

Values: Default: P
Possible Values: P or S

Display: **echo \$AIXTHREAD_SCOPE** (this is turned on internally, so the initial default value will not be seen with the **echo** command)

Change: **AIXTHREAD_SCOPE={P/S}**
export AIXTHREAD_SCOPE
Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **AIXTHREAD_SCOPE={P/S}** command to the **/etc/environment** file.

Diagnosis: If fewer threads are being dispatched than expected, then system scope should be tried.

Tuning: Tests on AIX 4.3.2 have shown that certain applications can perform much better with system based contention scope (S). The use of this environment variable impacts only those threads created with the default attribute. The default attribute is employed when the *attr* parameter to **pthread_create** is NULL.

Refer to: Thread Environment Variables

9. AIXTHREAD_SLPRATIO (AIX 4.3 and later)

Purpose: Controls the number of kernel threads that should be held in reserve for sleeping threads.

Values: Default: 1:12
Range: Two positive values (*k:p*), where k is the number of kernel threads that should be held in reserve for p sleeping pthreads

Display: **echo \$AIXTHREAD_SLPRATIO** (this is turned on internally, so the initial default value will not be seen with the **echo** command)

Change: **AIXTHREAD_SLPRATIO=k:p**
export AIXTHREAD_SLPRATIO
Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **AIXTHREAD_SLPRATIO=k:p** command to the **/etc/environment** file.

Diagnosis: N/A

Tuning: In general, fewer kernel threads are required to support sleeping pthreads, because they are generally woken one at a time. This conserves kernel resources.

Refer to: Variables for Process-Wide Contention Scope

10. MALLOCBUCKETS (Version 4.3.3.25 and later)

Purpose: Enables buckets-based extension in the default memory allocator which may enhance performance of applications that issue large numbers of small allocation requests.

Values: **MALLOCTYPE=buckets**

MALLOCBUCKETS=[[**number_of_buckets**:*n* | **bucket_sizing_factor**:*n* | **blocks_per_bucket**:*n* | **bucket_statistics**:[**stdout**|**stderr**|**pathname**]],...

The following table displays default values of MALLOCBUCKETS.

MALLOCBUCKETS Default Values	
MALLOCBUCKETS Options	Default Value
number_of_buckets ¹	16
bucket_sizing_factor (32-bit) ²	32
bucket_sizing_factor (64-bit) ³	64
blocks_per_bucket	1024 ⁴

Notes:

1. The minimum value allowed is 1. The maximum value allowed is 128.
2. For 32-bit implementations, the value specified for **bucket_sizing_factor** must be a multiple of 8.
3. For 64-bit implementations, the value specified for **bucket_sizing_factor** must be a multiple of 16.
4. The **bucket_statistics** option is disabled by default.

Display: **echo \$MALLOCBUCKETS; echo \$MALLOCTYPE**

Change: Use the shell specific method of exporting the environment variables.

Diagnosis: If malloc performance is slow and many small malloc requests are issued, this feature may enhance performance.

Tuning: To enable malloc buckets, the **MALLOCTYPE** environment variable has to be set to the value "buckets".

The **MALLOCBUCKETS** environment variable may be used to change the default configuration of the malloc buckets, although the default values should be sufficient for most applications.

The **number_of_buckets:n** option can be used to specify the number of buckets available per heap, where *n* is the number of buckets. The value specified for *n* will apply to all available heaps.

The **bucket_sizing_factor:n** option can be used to specify the bucket sizing factor, where *n* is the bucket sizing factor in bytes.

The **blocks_per_bucket:n** option can be used to specify the number of blocks initially contained in each bucket, where *n* is the number of blocks. This value is applied to all of the buckets. The value of *n* is also used to determine how many blocks to add when a bucket is automatically enlarged because all of its blocks have been allocated.

The **bucket_statistics** option will cause the malloc subsystem to output a statistical summary for malloc buckets upon typical termination of each process that calls the malloc subsystem while malloc buckets is enabled. This summary will show buckets configuration information and the number of allocation requests processed for each bucket. If multiple heaps have been enabled by way of malloc multiheap, the number of allocation requests shown for each bucket will be the sum of all allocation requests processed for that bucket for all heaps.

The buckets statistical summary will be written to one of the following output destinations, as specified with the **bucket_statistics** option.

stdout	Standard output
stderr	Standard error
pathname	A user-specified pathname

If a user-specified pathname is provided, statistical output will be appended to the existing contents of the file (if any). Avoid using standard output as the output destination for a process whose output is piped as input into another process.

Refer to: Malloc Buckets

11. MALLOCMULTIHEAP (AIX 4.3.1 and later)

Purpose: Controls the number of heaps within the process private segment.

Values: Default: 16 for 4.3.1 and 4.3.2, 32 for 4.3.3 and later
Range: A positive number between 1 and 32)

Display: **echo \$MALLOCMULTIHEAP** (this is turned on internally, so the initial default value will not be seen with the **echo** command)

Change: **MALLOCMULTIHEAP=[[heaps:n | considersize],...]**
export MALLOCMULTIHEAP

Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **MALLOCMULTIHEAP=[[heaps:n | considersize],...]** command to the **/etc/environment** file.

Diagnosis: Look for lock contention on the malloc lock (located in segment F) or fewer than expected runnable threads.

Tuning: Smaller number of heaps can help reduce size of the process. Certain multithreaded user processes which use the malloc subsystem heavily may obtain better performance by exporting the environment variable **MALLOCMULTIHEAP=1** before starting the application.

The potential performance enhancement is particularly likely for multithreaded C++ programs, because these may make use of the malloc subsystem whenever a constructor or destructor is called.

Any available performance enhancement will be most evident when the multithreaded user process is running on an SMP system, and particularly when system scope threads are used (M:N ratio of 1:1). However, in some cases, enhancement may also be evident under other conditions, and on uniprocessors.

If the **considersize** option is specified, an alternate heap selection algorithm is used that tries to select an available heap that has enough free space to handle the request. This may minimize the working set size of the process by reducing the number of **sbrk()** calls. However, there is a bit more processing time required for this algorithm.

Refer to: Thread Environment Variables

12. SPINLOOPTIME

Purpose: Controls the number of times to retry a busy lock before yielding to another processor (only for libpthreads).

Values: Default: 1 on uniprocessors, 40 on multiprocessors
Range: A positive integer

Display: **echo \$SPINLOOPTIME** (this is turned on internally, so the initial default value will not be seen with the **echo** command)

Change: **SPINLOOPTIME=*n***
export SPINLOOPTIME
Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **SPINLOOPTIME=*n*** command to the **/etc/environment** file.

Diagnosis: If threads are going to sleep often (lot of idle time), then the **SPINLOOPTIME** may not be high enough.

Tuning: Increasing the value from default of 40 on multiprocessor systems might be of benefit if there is pthread mutex contention.

Refer to: Thread Environment Variables

13. YIELDLOOPTIME

Purpose: Controls the number of times to yield the processor before blocking on a busy lock (only for libpthreads). The processor is yielded to another kernel thread, assuming there is another runnable kernel thread with sufficient priority.

Values: Default: 0
Range: A positive value

Display: **echo \$YIELDLOOPTIME** (this is turned on internally, so the initial default value will not be seen with the **echo** command)

Change: **YIELDLOOPTIME=*n***
export YIELDLOOPTIME
Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **YIELDLOOPTIME=*n*** command to the **/etc/environment** file.

Diagnosis: If threads are going to sleep often (lot of idle time), then the **YIELDLOOPTIME** may not be high enough.

Tuning: Increasing the value from default value of 0 may benefit if you do not want the threads to go to sleep when waiting for locks.

Refer to: Thread Environment Variables

Miscellaneous Tunable Parameters

Following is a list of *miscellaneous parameters* that can be tuned:

1. EXTSHM (AIX 4.2.1 and later)

Purpose: Turns on the extended shared memory facility.

Values: Default: Not set
Possible Value: ON

Display: **echo \$EXTSHM**

Change: **EXTSHM=ON**
export EXTSHM

Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **EXTSHM=ON** command to the **/etc/environment** file.

Diagnosis: N/A

Tuning: Setting value to ON will allow a process to allocate shared memory segments as small as 1 byte (though this will be rounded up to the nearest page); this effectively removes the limitation of 11 user shared memory segments. Maximum size of all segments together can still only be 2.75 GB worth of memory for 32-bit processes. 64-bit processes do not need to set this variable since a very large number of segments is available. Some restrictions apply for processes that set this variable, and these restrictions are the same as with processes that use mmap buffers.

Refer to: Extended Shared Memory (EXTSHM)

2. LDR_CNTRL

Purpose: Allows tuning of the kernel loader.

Values: Default: Not set
Possible Values: PREREAD_SHLIB, LOADPUBLIC, IGNOREUNLOAD, USERREGS, MAXDATA, DSA

Display: **echo \$LDR_CNTRL**

Change: **LDR_CNTRL={PREREAD_SHLIB | LOADPUBLIC | ...}**
export LDR_CNTRL

Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **LDR_CNTRL={PREREAD_SHLIB | LOADPUBLIC | ...}** command to the **/etc/environment** file.

Diagnosis: N/A

Tuning: The **LDR_CNTRL** environment variable can be used to control one or more aspects of the system loader behavior. You can specify multiple options with the **LDR_CNTRL** variable. When doing this, separate the options using an @ character (that is, **LDR_CNTRL=PREREAD_SHLIB@LOADPUBLIC**).

Specifying the **PREREAD_SHLIB** option will cause entire libraries to be read as soon as they are accessed. With VMM readahead tuned, a library can be read in from disk and be cached in memory by the time the program starts to access its pages. While this method can use more memory, it can enhance performance of programs that use many shared library pages providing the access pattern is non-sequential. (for example, Catia).

Specifying the **LOADPUBLIC** option directs the system loader to load all modules requested by an application into the global shared library segment. If a module cannot be loaded publicly into the global shared library segment then it is loaded privately for the application.

Specifying the **IGNOREUNLOAD** option will cause modules that are marked to be unloaded and used again (if the module has not been unloaded already). As a side effect of this option, you can end up with two different data instances for the module.

Specifying the **USERREGS** option will tell the system to save all general-purpose user registers across system calls made by an application. This can be helpful in applications doing garbage collection.

The **MAXDATA** option for the **LDR_CNTRL** variable allows you to set or override maxdata value specified in an executable. If you want to use Large Program Support with a data heap size of 0x30000000, then specify **LDR_CNTRL=MAXDATA=0x30000000**. To turn off Large Program Support, specify **LDR_CNTRL=MAXDATA=0**.

Specifying the **DSA** (Dynamic Segment Allocation) option will tell the system loader to run applications using Very Large Program Support. The **DSA** option is only valid for 32-bit applications with a non-zero maxdata value.

3. NODISCLAIM

Purpose: Controls how calls to **free()** are being handled. When **PSALLOC** is set to *early*, all **free()** calls result in a **disclaim()** system call. When **NODISCLAIM** is set to True, this does not occur.

Values: Default: Not set
Possible Value: True

Display: **echo \$NODISCLAIM**

Change: **NODISCLAIM=true**
export NODISCLAIM
Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **NODISCLAIM=true** command to the **/etc/environment** file.

Diagnosis: If number of **disclaim()** system calls is very high, you may want to set this variable.

Tuning: Setting this variable will eliminate calls to **disclaim()** from **free()** if **PSALLOC** is set to early.

Refer to: Early Page Space Allocation

4. NSORDER

Purpose: Overwrites the set name resolution search order.

Values: Default: bind, nis, local
Possible Values: bind, local, nis, bind4, bind6, local4, local6, nis4, or nis6

Display: **echo \$NSORDER** (this is turned on internally, so the initial default value will not be seen with the **echo** command)

Change: **NSORDER=value, value, ...**
export NSORDER
Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding **NSORDER=value** command to the **/etc/environment** file.

Diagnosis: N/A

Tuning: **NSORDER** overrides the **/etc/netsvc.conf** file.

Refer to: Tuning Name Resolution

5. PSALLOC

Purpose:	Sets the PSALLOC environment variable to determine the paging-space allocation policy.
Values:	Default: Not set Possible Value: early
Display:	echo \$PSALLOC
Change:	PSALLOC=early export PSALLOC Change takes effect immediately in this shell. Change is effective until logging out of this shell. Permanent change is made by adding PSALLOC=early command to the /etc/environment file.
Diagnosis:	N/A
Tuning:	To ensure that a process is not killed due to low paging conditions, this process can preallocate paging space by using the Early Page Space Allocation policy. However, this may result in wasted paging space. You may also want to set the NODISCLAIM environment variable.

Refer to: Allocation and Reclamation of Paging Space Slots and Early Page Space Allocation

6. mount -o nointegrity

Purpose:	A new mount option (nointegrity) may enhance local file system performance for certain write-intensive applications. This optimization basically eliminates writes to the JFS log. Note that the enhanced performance is achieved at the expense of metadata integrity. Therefore, use this option with extreme caution because a system crash can make a file system mounted with this option unrecoverable. Nevertheless, certain classes of applications do not require file data to remain consistent after a system crash, and these may benefit from using the nointegrity option. Two examples in which a nointegrity file system may be beneficial is for compiler temporary files, and for doing a nonmigration or mksysb installation.
-----------------	---

Refer to: Reorganizing JFS Log and Log Logical Volumes

Kernel Tunable Parameters

Following are kernel parameters, grouped into the following sections:

- Scheduler Tunable Parameters
- Memory Load Control Tunable Parameters
- Virtual Memory Manager and File System Tunable Parameters
- Asynchronous I/O Tunable Parameters
- Logical Volume Manager Tunable Parameters
- Disk and Disk Adapter Tunable Parameters
- Interprocess Communication Tunable Parameters

Scheduler Tunable Parameters

1. AFFINITY_LIM (Version 4.3.3.1 and later)

Purpose:	Sets the number of intervening dispatches after which the SCHED_FIFO2 policy no longer favors a thread.
Values:	Default: 7; Range: 0 to 100
Display:	schedtune
Change:	schedtune -a NewValue Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding schedtune command to /etc/inittab .

Diagnosis: N/A
Tuning: Once a thread is running with SCHED_FIFO2 policy, tuning of this variable may or may not have an effect on the performance of the thread and workload. Ideal values should be determined by trial and error.
Refer to: Scheduling Policy for Threads

2. `idle_migration_barrier` (Version 4.3.3.1 and later)

Purpose: Used to determine when threads can be migrated to other processors.
Values: Default: 4; Range: 0 to 100
Display: `schedtune`
Change: `schedtune -b NewValue`
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding `schedtune` command to `/etc/inittab`.
Diagnosis: N/A
Tuning: This value is divided by 16 and then multiplied by the load average. The resulting value is used to determine if jobs should be migrated to other nodes (essentially does load balancing).

3. `fixed_pri_global`

Purpose: Keep fixed priority threads on global run queue. Available in operating system version 4.3.3.1 and later releases.
Values: Default: 0; Range: 0 or 1
Display: `schedtune`
Change: `schedtune -F NewValue`
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding `schedtune` command to `/etc/inittab`.
Diagnosis: N/A
Tuning: If 1, then fixed priority threads are placed on the global run queue.
Refer to: Scheduler Run Queue

4. `MAXSPIN` (AIX 4.3.1 and later)

Purpose: Sets the number of times to spin on a kernel lock before going to sleep.
Values: Default: 1 on uniprocessor systems,
16384 on MP systems (AIX 4.3.1 and later),
-1 on MP systems that are at releases older than 4.3.1, which means to spin up to 2^{32} times
Range: -1 to 2^{32}
Display: `schedtune`
Change: `schedtune -s NewValue`
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding `schedtune` command to `/etc/inittab`.
Diagnosis: N/A
Tuning: Increasing the value or setting it to -1 on MP systems may reduce idle time; however, it may also waste CPU time in some situations. Increasing it on uniprocessor systems is not recommended.
Refer to: The `schedtune -s` Command

5. `maxuproc`

Purpose: Specifies the maximum number of processes per user ID.
Values: Default: 40; Range: 1 to 131072

Display: `lsattr -E -l sys0 -a maxuproc`

Change: `chdev -l sys0 -a maxuproc=NewValue`
 Change takes effect immediately and is preserved over boot. If value is reduced, then it goes into effect only after a system boot.

Diagnosis: Users cannot fork any additional processes.

Tuning: This is a safeguard to prevent users from creating too many processes.

Refer to: Responding to PDT Report Messages

6. ncargs

Purpose: Specifies the maximum allowable size of the ARG/ENV list (in 4KB blocks) when running subroutines.

Values: Default: 6; Range: 6 to 128

Display: `lsattr -E -l sys0 -a ncargs`

Change: `chdev -l sys0 -a ncargs=NewValue`
 Change takes effect immediately and is preserved over boot.

Diagnosis: Users cannot execute any additional processes because the argument list passed to the **exec()** system call is too long.

Tuning: This is a mechanism to prevent the **exec()** subroutines from failing if the argument list is too long. Please note that tuning to a higher **ncargs** value puts additional constraints on system memory resources.

7. pacefork

Purpose: The number of clock ticks to wait before retrying a failed fork call that has failed for lack of paging space.

Values: Default: 10 (10-millisecond clock ticks), Range: 10 to *n* clock ticks

Display: `schedtune`

Change: `schedtune -f NewValue`
 Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **schedtune** command to **/etc/inittab**.

Diagnosis: System is running out of paging space and process cannot be forked.

Tuning: The system will retry a failed fork five times. For example, if a **fork()** subroutine call fails because there is not enough paging space available to create a new process, the system retries the call after waiting the specified number of clock ticks.

Refer to: Tuning the fork() Retry Interval Parameter with schedtune

8. RT_GRQ (Version 4.3.3.1 and later)

Purpose: Causes thread to be put on a global run queue rather than on a per-CPU run queue.

Values: Default: Not set; Range: ON, OFF

Display: `echo $RT_GRQ`

Change: `RT_GRQ={OFF/ON}`
`export RT_GRQ`
 Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding `RT_GRQ={ON/OFF}` command to the **/etc/environment** file.

Diagnosis: N/A

Tuning: May be tuned on multiprocessor systems. Set to ON, will cause the thread to be put on a global run queue. In that case, the global run queue is searched to see which thread has the best priority. This might allow to get the thread dispatched sooner and can improve performance for threads that are running SCHED_OTHER, and are interrupt driven.

Refer to: Scheduler Run Queue

9. RT_MPC (AIX 4.3.3 and later)

Purpose: When running the kernel in real-time mode (see **bosdebug** command), an MPC can be sent to a different CPU to interrupt it if a better priority thread is runnable so that this thread can be dispatched immediately.

Values: Default: Not set; Range: ON

Display: **echo \$RT_MPC**

Change: **RT_MPC=ON**
export RT_MPC
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **RT_MPC=ON** command to the **/etc/environment** file.

Diagnosis: N/A

10. sched_D

Purpose: Sets the short term CPU usage decay rate.

Values: Default: 16; Range: 0 to 32

Display: **schedtune**

Change: **schedtune -d NewValue**
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **schedtune** command to **/etc/inittab**.

Diagnosis: N/A

Tuning: The default is to decay short-term CPU usage by 1/2 (16/32) every second. Decreasing this value enables foreground processes to avoid competition with background processes for a longer time.

Refer to: Tuning the Thread-Priority-Value Calculation

11. sched_R

Purpose: Sets the weighting factor for short-term CPU usage in priority calculations.

Values: Default: 16; Range: 0 to 32

Display: **schedtune**

Change: **schedtune -r NewValue**
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **schedtune** command to **/etc/inittab**.

Diagnosis: Run: **ps al**. If you find that the PRI column has priority values for foreground processes (those with NI values of 20) that are higher than the PRI values of some background processes (NI values > 20), you can reduce the *r* value.

Tuning: The default is to include 1/2 (16/32) of the short term CPU usage in the priority calculation. Decreasing this value makes it easier for foreground processes to compete.

Refer to: Tuning the Thread-Priority-Value Calculation

12. timeslice

Purpose: The number of clock ticks a thread can run before it is put back on the run queue.

Values: Default: 1; Range: A positive integer value

Display: **schedtune**
Change: **schedtune -t *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **schedtune** command to **/etc/inittab**.
Diagnosis: N/A
Tuning: Increasing this value can reduce overhead of dispatching threads. The value refers to the total number of clock ticks in a timeslice and only affects fixed-priority processes.
Refer to: Modifying the Scheduler Time Slice with the schedtune Command

13. usDELTA

Purpose: Used to adjust system clock with each clock tick in the correction range -1 to +1 seconds.
Values: Default: 100; Range: 1 to 100
Display: **schedtune**
Change: **schedtune -c *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **schedtune** command to **/etc/inittab**.
Diagnosis: N/A
Tuning: This is used to adjust clock drifts.

Memory Load Control Tunable Parameters

1. v_exempt_secs

Purpose: Sets the number of seconds that a recently resumed process that was previously suspended is exempt from suspension.
Values: Default: 2
Display: **schedtune**
Change: **schedtune -e *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **schedtune** command to **/etc/inittab**.
Diagnosis: N/A
Tuning: This parameter is only examined if thrashing is occurring.
Refer to: VMM Memory Load Control Facility and Tuning VMM Memory Load Control with the schedtune Command

2. v_min_process

Purpose: Sets the minimum number of processes that are exempt from suspension.
Values: Default: 2
Display: **schedtune**
Change: **schedtune -m *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **schedtune** command to **/etc/inittab**.
Diagnosis: N/A
Tuning: This number is in addition to kernel processes, processes with fixed priority less than 60, processes with pinned memory, or processes awaiting events. This parameter is only examined if there are threads on the suspended queue.
Refer to: VMM Memory Load Control Facility and Tuning VMM Memory Load Control with the schedtune Command

3. v_repage_hi

Purpose: Sets the systemwide criteria used to determine when process suspension begins and ends (system is thrashing).

Values: Default: 6 unless system RAM is 128 MB or more (in this case it is 0)

Display: **schedtune**

Change: **schedtune -h *NewValue***

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **schedtune** command to **/etc/inittab**.

Diagnosis: If $v_repage_hi * page_outs/sec$ is $> page_steals$, then processes may get suspended.

Tuning: If system is paging and causing scheduler to think it is thrashing but thrashing is not actually occurring, then it may be useful to desensitize the algorithm by decreasing the **-h** value or setting it to 0.

Refer to: VMM Memory Load Control Facility and Tuning VMM Memory Load Control with the schedtune Command

4. v_repage_proc

Purpose: Sets the per-process criterion used to determine which processes to suspend

Values: Default: 4

Display: **schedtune**

Change: **schedtune -p *NewValue***

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **schedtune** command to **/etc/inittab**.

Diagnosis: **Diagnosis:**

Tuning: This requires a higher level of repaging by a given process before it is a candidate for suspension by memory load control. This parameter is examined only if thrashing is occurring.

Refer to: VMM Memory Load Control Facility and Tuning VMM Memory Load Control with the schedtune Command

5. v_sec_wait

Purpose: Sets the number of seconds to wait after thrashing ends before making suspended processes runnable.

Values: Default: 1

Display: **schedtune**

Change: **schedtune -w *NewValue***

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **schedtune** command to **/etc/inittab**.

Diagnosis: N/A

Tuning: This parameter is examined only if thrashing is occurring.

Refer to: VMM Memory Load Control Facility and Tuning VMM Memory Load Control with the schedtune Command

Virtual Memory Manager and File System Tunable Parameters

1. defps (AIX 4.3.2 and later)

Purpose: Turns on/off Deferred Page Space Allocation (DPSA) policy.

Values: Default: 1; Range: 0 or 1; Value of 1 means DPSA is on

Display: **vmtune**

Change: `vmtune -d NewValue`
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding `vmtune` command to `/etc/inittab`.

Diagnosis: N/A

Tuning: May be useful to turn off DPSA policy if you are concerned about page-space overcommitment. Having the value on reduces paging space requirements.

Refer to: Choosing between LPSA and DPSA with the vmtune Command

2. Irubucket

Purpose: Specifies the number of memory frames per bucket. The page-replacement algorithm divides real memory into buckets of frames. On systems with multiple memory pools, the `Irubucket` parameter is per memory pool.

Values: Default: 131072 frames; Range: 1 to `total_number_of_memory_frames`

Display: `vmtune`

Change: `vmtune -I NewValue`
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding `vmtune` command to `/etc/inittab`.

Diagnosis: N/A

Tuning: Tuning this parameter is not recommended on most systems. Instead of scanning every frame in the system looking for a free frame, the page replacement algorithm scans through the contents of a bucket and scans the same bucket for the second pass before going on to the next bucket.

Refer to: Tuning Irubucket to Reduce Memory Scanning Overhead

3. maxbuf

Purpose: Number of (4 KB) pages in the block-I/O buffer cache.

Values: Default: 20, Range: 20 to 1000

Display: `lsattr -E -l sys0 -a maxbuf`

Change: `chdev -l sys0 -a maxbuf=NewValue`
Change is effective immediately and is permanent. If the `-T` flag is used, the change is immediate and lasts until the next boot. If the `-P` flag is used, the change is deferred until the next boot and is permanent.

Diagnosis: If the `sar -b` command shows breads or bwrites with `%rcache` and `%wcache` being low, you might want to tune this parameter.

Tuning: This parameter normally has little performance effect on systems, where ordinary I/O does not use the block-I/O buffer cache.

4. maxfree

Purpose: Specifies the number of frames on the free list at which page-stealing is to stop.

Values: Default: MIN (`#of memory pages/128, 128`); Range: 16 to 204800

Display: `vmtune`

Change: `vmtune -F NewValue`
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding `vmtune` command to `/etc/inittab`.

Diagnosis: Observe free-list-size changes with `vmstat n`.

Tuning: If **vmstat n** shows free-list size frequently driven below **minfree** by application demands, increase **maxfree** to reduce calls to replenish the free list. Generally, keep **maxfree - minfree** equal to or less than 100. Setting the value too high causes page replacement to run for a longer period of time. Value must be at least 8 greater than **minfree**.

Refer to: Tuning VMM Page Replacement with the vmtune Command

maxperm

Purpose: Specifies the point above which the page-stealing algorithm steals only file pages.

Values: Default: $(\text{Total_Ram} - 4 \text{ MB}) * 0.8$ or $(\text{\# of total memory frames}) - 1024 * 0.8$; Range: 1 to 100

Display: **vmtune**

Change: **vmtune -P *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: Monitor disk I/O with **iostat n**.

Tuning: This value is expressed as a percentage of the total real-memory page frames in the system. Reducing this value may reduce or eliminate page replacement of working storage pages caused by high number of file page accesses. Increasing this value may help NFS servers that are mostly read-only. For example, if some files are known to be read repetitively, and I/O rates do not decrease with time from startup, **maxperm** may be too low.

Refer to: Tuning VMM Page Replacement with the vmtune Command

maxpgahead

Purpose: Specifies the maximum number of pages to be read ahead when processing a sequentially accessed file.

Values: Default: 8 (the default should be a power of two and should be greater than or equal to **minpgahead**); Range: 0 to 4096

Display: **vmtune**

Change: **vmtune -R *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: Observe the elapsed execution time of critical sequential-I/O-dependent applications with the **time** command.

Tuning: Because of limitations in the kernel, do not exceed 512 as the maximum value used. The difference between **minfree** and **maxfree** should always be equal to or greater than **maxpgahead**. If execution time decreases with higher **maxpgahead**, observe other applications to ensure that their performance has not deteriorated.

Refer to: Sequential Read-Ahead

maxpin

Purpose: Specifies the maximum percentage of real memory that can be pinned.

Values: Default: 80 percent; Range: 1 to 99

Display: **vmtune**

Change: **vmtune -M *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: Cannot pin memory, although free memory is available.

Tuning: If this value is changed, the new value should ensure that at least 4 MB of real memory will be left uncommitted for use by the kernel. The **maxpin** values must be greater than one and less than 100. The value under **maxpin** is converted to a percentage at the end of the output of the **vm tune** command. Change this parameter only in extreme situations, such as maximum-load benchmarking.

maxpout

Purpose: Specifies the maximum number of pending I/Os to a file.

Values: Default: 0 (no checking); Range: 0 to n (n should be a multiple of 4, plus 1)

Display: **lsattr -E -l sys0 -a maxpout**

Change: **chdev -l sys0 -a maxpout=NewValue**

Change is effective immediately and is permanent. If the **-T** flag is used, the change is immediate and lasts until the next boot. If the **-P** flag is used, the change is deferred until the next boot and is permanent.

Diagnosis: If foreground response time sometimes deteriorates when programs with large amounts of sequential disk output are running, sequential output may need to be paced.

Tuning: Set **maxpout** to 33 and **minpout** to 16. If sequential performance deteriorates unacceptably, increase one or both. If foreground performance is still unacceptable, decrease both.

Refer to: Using Disk-I/O Pacing

maxrandwrt (AIX 4.1.3 and later)

Purpose: Specifies a threshold (in 4 KB pages) for random writes to accumulate in RAM before subsequent pages are flushed to disk by the write-behind algorithm. The random write-behind threshold is on a per-file basis.

Values: Default: 0, Range: 0 to largest_file_size_in_pages

Display: **vm tune**

Change: **vm tune -W NewValue**

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vm tune** command to **/etc/inittab**.

Diagnosis: **vmstat n** shows page out and I/O wait peaks on regular intervals (usually when the **sync** daemon is writing pages to disk).

Tuning: Useful to set this value to 1 or higher if too much I/O occurs when **syncd** runs. Default is to have random writes stay in RAM until a **sync** operation. Setting **maxrandwrt** ensures these writes get flushed to disk before the **sync** operation has to occur. However, this could degrade performance because the file is then being flushed each time. Tune this option to favor interactive response time over throughput. After the threshold is reached, all subsequent pages are then immediately flushed to disk. The pages up to the threshold value stay in RAM until a **sync** operation. A value of 0 disables random write-behind.

Refer to: VMM Write-Behind

mempools (AIX 4.3.3 and later)

Purpose: Changes the number of memory pools that will be configured at system boot time.

Values: Default: MAX (Number of CPUs/8, RAM in GB/16) but not more than the number of CPUs and not less than 1

Display: **vm tune**

Change: **vm tune -m NewValue**

Change takes effect at next boot and is permanent.

Diagnosis: N/A

Tuning: The change is written to the kernel file if it is an MP kernel (the change is not allowed on a UP kernel). A value of 0 will restore the default number of memory pools. By default, the **vmtune -m** command will write to **/usr/lib/boot/unix_mp**, but this can be changed with the command **vmtune -U <path to unix file>**. Before changing the kernel file, the **vmtune** command will save the original file as *<name of original file>.sav*.

Refer to: Tuning Memory Pools

minfree

Purpose: Specifies the minimum number of frames on the free list at which the VMM starts to steal pages to replenish the free list.

Values: Default: maxfree - 8; Range: 8 to 204800

Display: **vmtune**

Change: **vmtune -f *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: **vmstat n**

Tuning: Page replacement occurs when the number of free frames reaches **minfree**. If processes are being delayed by page stealing, increase **minfree** to improve response time. The difference between **minfree** and **maxfree** should always be equal to or greater than **maxpgahead**.

Refer to: Tuning VMM Page Replacement with the vmtune Command

minperm

Purpose: Specifies the point below which the page-stealer will steal file or computational pages regardless of repaging rates.

Values: Default: (Total_RAM - 4 MB)*0.2 or ((number of total memory frames) - 1024)*0.2; Range: 1 to 100

Display: **vmtune**

Change: **vmtune -p *NewValue_as_a_percentage***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: Monitor disk I/O with **iostat n**.

Tuning: Can be useful to decrease this parameter if large number of file pages in memory is causing working storage pages to be replaced. On the other hand, if some files are known to be read repetitively, and I/O rates do not decrease with time from startup, **minperm** may be too low.

Refer to: Tuning VMM Page Replacement with the vmtune Command

minpgahead

Purpose: Specifies the number of pages with which sequential read-ahead starts.

Values: Default: 2; Range: 0 to 4096 (should be a power of two)

Display: **vmtune**

Change: **vmtune -r *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: Observe the elapsed execution time of critical sequential-I/O-dependent applications with **time** command.

Tuning: Useful to increase if there are lots of large sequential accesses. Observe other applications to ensure that their performance has not deteriorated. Value of 0 may be useful if I/O pattern is purely random.

Refer to: Sequential Read-Ahead

minpout

Purpose: Specifies the point at which programs that have reached **maxpout** can resume writing to the file.

Values: Default: 0 (no checking); Range: 0 to *n* (*n* should be a multiple of 4 and should be at least 4 less than **maxpout**)

Display: **lsattr -E -l sys0 -a minpout**

Change: **chdev -l sys0 -a minpout=NewValue**

Change is effective immediately and is permanent. If the **-T** flag is used, the change is immediate and lasts until the next boot. If the **-P** flag is used, the change is deferred until the next boot and is permanent.

Diagnosis: If foreground response time sometimes deteriorates when programs with large amounts of sequential disk output are running, sequential output may need to be paced.

Tuning: Set **maxpout** to 33 and **minpout** to 16. If sequential performance deteriorates unacceptably, increase one or both. If foreground performance is still unacceptable, decrease both.

Refer to: Using Disk-I/O Pacing

nokillroot (Version 4.3.3.0 to 4.3.3.1)

Purpose: If set to 1, it will exempt root-owned processes from getting killed due to low page-space conditions.

Values: Default: 0 (off); Range 0 or 1

Display: **vmtune**

Change: **vmtune -n NewValue**

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: System out of paging space and system administrator's processes are getting killed.

Tuning: Set to 1 in order to protect system admin processes from getting killed or ensure there is sufficient paging space available.

Refer to: Choosing npswarn and npskill Settings

nokilluid (Version 4.3.3.2 and later)

Purpose: User IDs lower than this value will be exempt from getting killed due to low page-space conditions.

Values: Default: 0 (off); Range: Any positive integer

Display: **vmtune**

Change: **vmtune -k NewValue**

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: System out of paging space and system administrator's processes are getting killed.

Tuning: Set to 1 in order to protect specific user ID processes from getting killed due to low page space or ensure there is sufficient paging space available.

Refer to: Choosing npswarn and npskill Settings

npskill

- Purpose:** Specifies the number of free paging-space pages at which the operating system begins killing processes.
- Values:** Default: MAX (64, number_of_paging_space_pages/128)
- Display:** **vmtune**
- Change:** **vmtune -n *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.
- Diagnosis:** N/A
- Tuning:** The **npskill** value must be greater than zero and less than the total number of paging space pages on the system.

Refer to: Choosing npswarn and npskill Settings

npswarn

- Purpose:** Specifies the number of free paging-space pages at which the operating system begins sending the SIGDANGER signal to processes.
- Values:** Default: MAX (512,4*npskill)
- Display:** **vmtune**
- Change:** **vmtune -w *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.
- Diagnosis:** N/A
- Tuning:** The value of **npswarn** must be greater than zero and less than the total number of paging space pages on the system. Increase the value if you experience processes being killed because of low paging space.

Refer to: Choosing npswarn and npskill Settings

numclust

- Purpose:** Specifies the number of 16 k clusters processed by the sequential write-behind algorithm of the VMM.
- Values:** Default: 1 in AIX Version 4 to AIX 4.2; 0 in AIX 4.2.1; 1 in Version 4.3 and later; Range: 0 to any positive integer
- Display:** **vmtune**
- Change:** **vmtune -c *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.
- Diagnosis:** N/A
- Tuning:** Useful to increase if there is a need to keep more pages in RAM before scheduling them for I/O when the I/O pattern is sequential. May be appropriate to increase if striped logical volumes or disk arrays are being used.

Refer to: VMM Write-Behind

numfsbufs

- Purpose:** Specifies the number of file system bufstructs.
- Values:** Default: 93 (value is dependent on the size of the bufstruct)

Display: **vmtune**

Change: **vmtune -b *NewValue***
 Change takes effect when a file system is mounted. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**. File system must be remounted.

Diagnosis: N/A

Tuning: If the VMM must wait for a free bufstruct, it puts the process on the VMM wait list before the start I/O is issued and will wake it up once a bufstruct has become available. May be appropriate to increase if striped logical volumes or disk arrays are being used.

Refer to: Miscellaneous I/O Tuning Parameters

pagecoloring (Version 4.3.3.2 and later)

Purpose: Turns on (**-C 1**) or off (**-C 0**) page coloring in the VMM.

Values: Default: 0 (off); Range: 0 or 1

Display: **vmtune**

Change: **vmtune -C *NewValue***
 Change takes effect at next boot and is permanent.

Diagnosis: N/A

Tuning: This parameter is useful for some applications that run on machines that have a direct mapped cache. By default, the **vmtune -C** command will write to **/usr/lib/boot/unix_mp**, but this can be changed with the command **vmtune -U <path to unix file>**. Before changing the kernel file, the **vmtune** command will save the original file as **<name of original file>.sav**.

Paging Space Size

Purpose: The amount of disk space required to hold pages of working storage.

Values: Default: configuration-dependent; Range: 32 MB to *n* MB for hd6, 16 MB to *n* MB for non-hd6

Display: **lsps -a**

Change: **mkps** or **chps** or **smitty pgsp**
 Change takes effect immediately and is permanent. Paging space is not necessarily put into use immediately, however.

Diagnosis: Run: **lsps -a**. If processes have been killed for lack of paging space, monitor the situation with the **psdanger()** subroutine.

Tuning: If it appears that there is not enough paging space to handle the normal workload, add a new paging space on another physical volume or make the existing paging spaces larger.

Refer to: Placement and Sizes of Paging Spaces

pd_npages

Purpose: Specifies the number of pages that should be deleted in one chunk from RAM when a file is deleted.

Values: Default: largest file size in pages; Range: 1 to largest filesize_in_pages

Display: **vmtune**

Change: **vmtune -N *NewValue***
 Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: Real-time applications that experience sluggish response time while files are being deleted.

Tuning: Tuning this option is only useful for real-time applications. If real-time response is critical, adjusting this option may improve response time by spreading the removal of file pages from RAM more evenly over a workload.

Refer to: Miscellaneous I/O Tuning Parameters

strict_maxperm (AIX 4.3.3 and later)

Purpose: If set to 1, the **maxperm** value will be a hard limit on how much of RAM can be used as a persistent file cache.

Values: Default: 0 (off); Range 0 or 1

Display: **vmtune**

Change: **vmtune -h *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: Excessive page outs to page space caused by too many file pages in RAM.

Tuning: Set to 1 in order to make the **maxperm** value a hard limit (use in conjunction with the tuning of the **maxperm** parameter).

Refer to: Placing a Hard Limit on Persistent File Cache with strict_maxperm

sync_release_ilock

Purpose: If set, will cause a **sync()** to flush all I/O to a file without holding the i-node lock, and then use the i-node lock to do the commit.

Values: Default: 0 (off); Range 0 or 1

Display: **vmtune**

Change: **vmtune -s *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.

Diagnosis: I/O to a file is blocked when the **syncd** daemon is running.

Tuning: Default value of 0 means that the i-node lock is held while all dirty pages of a file are flushed.

Refer to: Tuning File Syncs

syncd Interval

Purpose: The time between **sync()** calls by **syncd**.

Values: Default: 60 ; Range: 1 to any positive integer

Display: **grep syncd /sbin/rc.boot**

Change: **vi /sbin/rc.boot**
Change takes effect at next boot and is permanent. An alternate method is to use the **kill** command to terminate the **syncd** daemon and restart it from the command line with the command **/usr/sbin/syncd interval**.

Diagnosis: I/O to a file is blocked when **syncd** is running.

Tuning: At its default level, this parameter has little performance cost. No change is recommended. Significant reductions in the **syncd** interval in the interests of data integrity (as for HACMP) could have adverse performance consequences.

Refer to: Using sync/fsync Calls

v_pinshm (AIX 4.3.3 and later)

- Purpose:** If set to 1, will allow pinning of shared memory segments.
- Values:** Default: 0 (off); Range 0 or 1
- Display:** **vmtune**
- Change:** **vmtune -S *NewValue***
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.
- Diagnosis:** Too much overhead in pinning or unpinning of AIO buffers from shared memory segments.
- Tuning:** Useful only if application also sets SHM_PIN flag when doing a **shmget()** call and if doing async I/O from shared memory segments

Refer to: Miscellaneous I/O Tuning Parameters

Asynchronous I/O Tunable Parameters

maxreqs

- Purpose:** Specifies the maximum number of asynchronous I/O requests that can be outstanding at any one time.
- Values:** Default: 4096; Range: 1 to AIO_MAX (**/usr/include/sys/limits.h**)
- Display:** **lsattr -E -l aio0 -a maxreqs**
- Change:** **chdev -l aio0 -a maxreqs=*NewValue***
Change is effective immediately and is permanent. If the **-T** flag is used, the change is immediate and lasts until the next boot. If the **-P** flag is used, the change is deferred until the next boot and is permanent.
- Diagnosis:** N/A
- Tuning:** This includes requests that are in progress, as well as those that are waiting to be started. The maximum number of asynchronous I/O requests cannot be less than the value of AIO_MAX, as defined in the **/usr/include/sys/limits.h** file, but can be greater. It would be appropriate for a system with a high volume of asynchronous I/O to have a maximum number of asynchronous I/O requests larger than AIO_MAX.

Refer to: Tuning Asynchronous Disk I/O

maxservers

- Purpose:** Specifies the maximum number of AIO **kprocs** that will be created.
- Values:** Default: 10
- Display:** **lsattr -E -l aio0 -a maxservers**
- Change:** **chdev -l aio0 -a maxservers=*NewValue***
Change is effective immediately and is permanent. If the **-T** flag is used, the change is immediate and lasts until the next boot. If the **-P** flag is used, the change is deferred until the next boot and is permanent.
- Diagnosis:** N/A
- Tuning:** This value limits the number of concurrent asynchronous I/O requests. The value should be about the same as the expected number of concurrent AIO requests. This tunable parameter only affects AIO on JFS file systems (or Virtual Shared Disks (VSD) before AIX 4.3.2).

Refer to: Tuning Asynchronous Disk I/O

minservers

- Purpose:** Specifies the number of AIO **kprocs** that will be created when the AIO kernel extension is loaded.
- Values:** Default: 1
- Display:** **lsattr -E -l aio0 -a maxservers**
- Change:** **chdev -l aio0 -a minservers=NewValue**
Change is effective immediately and is permanent. If the **-T** flag is used, the change is immediate and lasts until the next boot. If the **-P** flag is used, the change is deferred until the next boot and is permanent.
- Diagnosis:** N/A
- Tuning:** Making this a large number is not recommended, because each process takes up some memory. Leaving this number small is acceptable in most cases because AIO will create additional **kprocs** up to **maxservers** as needed. This tunable is only effective for AIO on JFS file systems (or VSDs before AIX 4.3.2).
- Refer to:** Tuning Asynchronous Disk I/O

Logical Volume Manager Tunable Parameters

hd_pbuf_cnt

- Purpose:** Specifies the total number of pbufs that the LVM uses.
- Values:** Default: 64 or more depending on the number of disks that have open logical volumes (default value is 64 + 16 for each additional physical disk with an open logical volume)
- Display:** **vmtune**
- Change:** **vmtune -B NewValue**
Change takes effect immediately. Change is effective until next boot. New value cannot be reduced because memory is pinned. Permanent change is made by adding **vmtune** command to **/etc/inittab**.
- Diagnosis:** Value of **hd_pendqblked** in **/dev/kmem** is non-zero, which indicates that LVM had to wait for pbufs.
- Tuning:** Useful to increase if there are a substantial number of simultaneous I/Os and value of **hd_pendqblked** is non-zero. To see value of **hd_pendqblked**, use the **vmtune -a** or **crash** command.
- Refer to:** Miscellaneous I/O Tuning Parameters

lvm_bufcnt (AIX Version 4)

- Purpose:** Specifies the number of LVM buffers for raw physical I/Os.
- Values:** Default: 9; Range: 1 to 64
- Display:** **vmtune**
- Change:** **vmtune -u NewValue**
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **vmtune** command to **/etc/inittab**.
- Diagnosis:** Applications performing large writes to striped raw logical volumes are not obtaining the desired throughput rate.

Tuning: LVM splits large raw I/Os into multiple buffers of 128 K a piece. Default value of 9 means that about 1 MB I/Os can be processed without waiting for more buffers.

If a system is configured to have striped raw logical volumes and is doing writes greater than 1.125 MB, increasing this value may help the throughput of the application.

If performing larger than 1 MB raw I/Os, it might be useful to increase this value.

Refer to: Miscellaneous I/O Tuning Parameters

Disk and Disk Adapter Tunable Parameters

Disk Adapter Outstanding-Requests Limit

Purpose: Maximum number of requests that can be outstanding on a SCSI bus. (Applies only to the SCSI-2 Fast/Wide Adapter.)

Values: Default: 40; Range: 40 to 128

Display: `lsattr -E -l scsin -a num_cmd_elems`

Change: `chdev -l scsin -a num_cmd_elems=NewValue`
Change is effective immediately and is permanent. If the **-T** flag is used, the change is immediate and lasts until the next boot. If the **-P** flag is used, the change is deferred until the next boot and is permanent.

Diagnosis: Applications performing large writes to striped raw logical volumes are not obtaining the desired throughput rate.

Tuning: Value should equal the number of physical drives (including those in disk arrays) on the SCSI bus, times the queue depth of the individual drives.

Disk Drive Queue Depth

Purpose: Maximum number of requests the disk device can hold in its queue.

Values: Default: IBM disks=3; Non-IBM disks=0; Range: specified by manufacturer

Display: `lsattr -E -l hdiskn`

Change: `chdev -l hdiskn -a q_type=simple -a queue_depth=NewValue`
Change is effective immediately and is permanent. If the **-T** flag is used, the change is immediate and lasts until the next boot. If the **-P** flag is used, the change is deferred until the next boot and is permanent.

Diagnosis: N/A

Tuning: If the non-IBM disk drive is capable of request-queuing, make this change to ensure that the operating system takes advantage of the capability.

Refer to: Setting SCSI-Adapter and Disk-Device Queue Limits

Interprocess Communication Tunable Parameters

msgmax

Purpose: Specifies maximum message size.

Values: Dynamic with maximum value of 4 MB

Display: N/A

Change: N/A

Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

msgmnb

Purpose: Specifies maximum number of bytes on queue.
Values: Dynamic with maximum value of 4 MB
Display: N/A
Change: N/A
Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

msgmni

Purpose: Specifies maximum number of message queue IDs.
Values: Dynamic with maximum value of 4096
Display: N/A
Change: N/A
Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

msgmnm

Purpose: Specifies maximum number of messages per queue.
Values: Dynamic with maximum value of 524288
Display: N/A
Change: N/A
Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

semaem

Purpose: Specifies maximum value for adjustment on exit.
Values: Dynamic with maximum value of 16384
Display: N/A
Change: N/A
Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

semmni

Purpose: Specifies maximum number of semaphore IDs.
Values: Dynamic with maximum value of 4096
Display: N/A
Change: N/A

Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

semmsl

Purpose: Specifies maximum number of semaphores per ID.
Values: Dynamic with maximum value of 65535
Display: N/A
Change: N/A
Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

semopm

Purpose: Specifies maximum number of operations per **semop()** call.
Values: Dynamic with maximum value of 1024
Display: N/A
Change: N/A
Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

semume

Purpose: Specifies maximum number of undo entries per process.
Values: Dynamic with maximum value of 1024
Display: N/A
Change: N/A
Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

semvmx

Purpose: Specifies maximum value of a semaphore.
Values: Dynamic with maximum value of 32767
Display: N/A
Change: N/A
Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

shmmax

Purpose: Specifies maximum shared memory segment size.
Values: Dynamic with maximum value of 256 MB for 32-bit processes and 0x80000000u for 64-bit
Display: N/A
Change: N/A

Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

shmmin

Purpose: Specifies minimum shared-memory-segment size.
Values: Dynamic with minimum value of 1
Display: N/A
Change: N/A
Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

shmmni

Purpose: Specifies maximum number of shared memory IDs.
Values: Dynamic with maximum value of 4096
Display: N/A
Change: N/A
Diagnosis: N/A
Tuning: Does not require tuning because it is dynamically adjusted as needed by the kernel.

Network Tunable Parameters

Following are network parameters, grouped into the following sections:

- Network Option Tunable Parameters
- NFS Option Tunable Parameters
- Streams Tunable Attributes

Network Option Tunable Parameters

arpqsize

Purpose: Specifies the maximum number of packets to queue while waiting for ARP responses.

Values: Default: 1

Display: **no -a** or **no -o arpqsize**

Change: **no -o arpqsize=NewValue**
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis: N/A

Tuning: This attribute is supported by Ethernet, 802.3, Token-Ring and FDDI interfaces. The **arpqsize** value is increased to a minimum value of 5 when path MTU discovery is enabled. The value will

not automatically decrease if path MTU discovery is subsequently disabled. This attribute applies to Versions 4.1.5, 4.2.1, and later. This is a run-time attribute.

Refer to:

Managing Tunable SP Parameters

arpt_killc

Purpose:

Specifies the time in minutes before a complete ARP entry will be deleted.

Values:

Default: 20

Display:

no -a or **no -o arpt_killc**

Change:

no -o arpt_killc=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

To reduce ARP activity in a stable network, you can increase **arpt_killc**. This is not a large effect. This is a run-time attribute.

arptab_bsiz

Purpose:

Specifies Address Resolution Protocol (ARP) table bucket size.

Values:

Default: 7

Display:

no -a or **no -o arptab_bsiz**

Change:

no -o arptab_bsiz=NewValue

Change is effective when the **netinet** kernel extension is loaded.

Diagnosis:

N/A

Tuning:

This is a load-time attribute and must be set in **/etc/rc.net** prior to the interfaces being defined.

Refer to:

SP System-Specific Tuning Recommendations

arptab_nb

Purpose:

Specifies the number of ARP table buckets.

Values:

Default: 25

Display:

no -a or **no -o arptab_nb**

Change:

no -o arptab_nb=NewValue

Change is effective when the **netinet** kernel extension is loaded.

Diagnosis:

N/A

Tuning:

This is a load-time attribute and must be set in **/etc/rc.net** prior to the interfaces being defined. Increase this value for systems that have a large number of clients or servers. The default provides for $25 \times 7 = 175$ ARP entries, but assumes an even task distribution.

Refer to:

SP System-Specific Tuning Recommendations

bcastping**Purpose:**

Allows response to ICMP echo packets to the broadcast address.

Values:

Default: 0 (off); Range 0 or 1 (on)

Display:

no -a or **no -o bcastping**

Change:

no -o bcastping=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a run-time attribute.

clean_partial_conns**Purpose:**

Specifies whether or not SYN (synchronizes the sequence number) attacks are being avoided.

Values:

Default: 0 (off); Range 0 or 1 (on)

Display:

no -a or **no -o clean_partial_conns**

Change:

no -o clean_partial_conns=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This option should be turned on for servers that need to protect against network attacks. If on, randomly removes partial connections to make room for new non-attack connections. This is a run-time attribute.

delayack

Purpose:

Delays acknowledgements (ACK) for certain TCP packets and attempts to "piggyback" them with the next packet sent instead.

Values:

Default: 0; Range: 0, 1, 2, 3

Display:

no -a or **no -o delayack**

Change:

no -o delayack=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This action will only be performed for connections whose destination port is specified in the list of the **delayackports** attribute. This can be used to increase performance when communicating with an HTTP server by reducing the total number of packets sent. The attribute can have one of four values:

- 0 No delays; normal operation
- 1 Delay the ACK for the server's SYN (Synchronizes the sequence numbers)
- 2 Delay the ACK for the server's FIN (Sender has reached the end of its byte stream)
- 3 Delay both the ACKs for the SYN and FIN

delayackports

Purpose:

Specifies the list of destination ports for which the operation defined by the **delayack** port option will be performed.

Values:

List of port numbers

Display:

no -a or **no -o delayackports**

Change:

no -o delayackports=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The attribute takes a list of up to ten ports, separated by commas and enclosed in curly braces. For example: **no -o delayackports={80,30080}**. To clear the list, set the option to {}.

directed_broadcast

Purpose:

Specifies whether to allow a directed broadcast to a gateway.

Values:

Default: 1 (on); Range: 0 or 1

Display:

no -a or **no -o directed_broadcast**

Change:

no -o directed_broadcast=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The value of 1 allows packets to be directed to a gateway to be broadcast on a network on the other side of the gateway. This is a run-time attribute.

extendednetstats**Purpose:**

Enables more extensive statistics for network memory services.

Values:

Default: 0 (off); Range: 0 or 1 (on)

Display:

no -a or **no -o extendednetstats**

Change:

no -o extendednetstats=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The default for this attribute is 0, for off, because these extra statistics cause a reduction in system performance. If these statistics are desired, it is recommended that this attribute be set to 1 in **/etc/rc.net**, as early as possible in the boot process. This is important, because some components may use the memory services, before this attribute is enabled. Thus the in-use fields for the statistics might not be correct.

fasttimo**Purpose:**

Allows you to set the millisecond delay for the TCP fast timeout timer. This timeout controls how often the system scans the TCP control blocks to send delayed acknowledgments.

Values:

Default: 200; Range: 50 to 200 milliseconds

Display:

no -a or **no -o fasttimo**

Change:

no -o fasttimo=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

Reducing this timer value may improve performance with some non-IBM systems. However, this may also result in slightly increased system utilization.

icmpaddressmask

Purpose:

Specifies whether the system responds to an ICMP address mask request.

Values:

Default: 0; Range: 0 or 1

Display:

no -a or **no -o icmpaddressmask**

Change:

no -o icmpaddressmask=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

If the default value 0 is set, the network silently ignores any ICMP address mask request that it receives. This is a run-time attribute.

ie5_old_multicast_mapping

Purpose:

Specifies IP multicasts on Token-Ring should be mapped to the broadcast address rather than a functional address when value 1 is used.

Values:

Default: 0 ; Range: 0 or 1

Display:

no -a or **no -o ie5_old_multicast_mapping**

Change:

no -o ie5_old_multicast_mapping=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a run-time attribute.

ifsize

Purpose:

Specifies the maximum number of network interface structures per interface.

Values:

Default: Number of interfaces in the system

Display:

no -a or **no -o ifsize**

Change:

no -o ifsize=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a load-time attribute. In operating system AIX 4.3, the **/etc/rc.net** script automatically determines the number of interfaces on the system and sets **ifsize** to that value. Therefore, there is no reason to alter this attribute.

Refer to:

Managing Tunable SP Parameters

inet_stack_size**Purpose:**

Specifies size of inet interrupt stack table in kilobytes.

Values:

Default: 16

Display:

no -a or **no -o inet_stack_size**

Change:

no -o inet_stack_size=NewValue

Size can only be changed by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is needed if you were running with unoptimized debug kernel or the **netinet** kernel extension. This is different from the pin more stack code (which is not configurable) because this is on interrupt. This attribute only needs to be changed if there is a system panic due to interrupt stack overflow.

ipforwarding**Purpose:**

Specifies whether the kernel should forward packets.

Values:

Default: 0 (off); Range: 0 or 1 (1 enables forwarding)

Display:

no -a or **no -o ipforwarding**

Change:

no -o ipforwarding=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a run-time attribute. Set it to 1, if the system is acting as an IP router.

Refer to:

The traceroute Command

ipfragttl**Purpose:**

Specifies the time to live for IP fragments in half-seconds.

Values:

Default: 60; Range: 60 to *n*

Display:

no -a or **no -o ipfragttl**

Change:

no -o ipfragttl=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

Fragments dropped after timeout (**netstat -p ip**).

Tuning:

If value of IP: fragments dropped after timeout is nonzero, increasing **ipfragttl** may reduce retransmissions. This is a run-time attribute.

Refer to:

IP Layer

ipignoreredirects

Purpose:

Specifies whether to process redirects that are received.

Values:

Default: 0 (does redirects); Range: 0 or 1 (1 ignores redirects)

Display:

no -a or **no -o ipignoreredirects**

Change:

no -o ipignoreredirects=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This option only applies to AIX 4.2.1 or later. This is a run-time attribute.

ipqmaxlen

Purpose:

Specifies the number of received packets that can be queued on the IP protocol input queue.

Values:

Default: 150; Range: 150 to *n*

Display:

no -a or **no -o ipqmaxlen**

Change:

no -o ipqmaxlen=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

Examine **ipintrq** overflows (**netstat -s**) or use **crash** to access IP input queue overflow counter.

Tuning:

This is a load-time attribute. Increase size if system is using a lot of loopback sessions. Most operating system network drives call IP directly and do not use the IP queue. On these devices increasing **ipqmaxlen** has no effect.

Refer to:

IP Layer and IP Protocol Performance Tuning Recommendations

ipssendredirects**Purpose:**

Specifies whether the kernel should send redirect signals.

Values:

Default: 1; Range: 0 or 1 (1 means send redirects; 0 means do not send redirects)

Display:

no -a or **no -o ipssendredirects**

Change:

no -o ipssendredirects=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a configuration decision with performance consequences. This is a run-time attribute.

ipssrcrouteforward**Purpose:**

Specifies whether the system forwards source-routed packets.

Values:

Default: 1 ; Range 0 or 1

Display:

no -a or **no -o ipssrcrouteforward**

Change:

no -o ipssrcrouteforward=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The default value of 1 allows the forwarding of source-routed packets. A value of 0 causes all source-routed packets that are not at their destinations to be discarded. This attribute only applies to AIX 4.2.1 or later.

ipssrcrouterrecv**Purpose:**

Specifies whether the system accepts source-routed packets.

Values:

Default: 0; Range: 0 or 1

Display:

no -a or **no -o ipssrcrouterrecv**

Change:

no -o ipssrcrouterrecv=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The default value of 0 causes all source-routed packets destined for this system to be discarded. A value of 1 allows source-routed packets to be received. This attribute only applies to AIX 4.2.1 or later.

ipsroutedsend**Purpose:**

Specifies whether applications can send source-routed packets.

Values:

Default: 1; Range: 0 or 1

Display:

no -a or **no -o ipsroutedsend**

Change:

no -o ipsroutedsend=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The default value of 1 allows source-routed packets to be sent. A value of 0 causes **setsockopt()** to return an error if an application attempts to set the source routing option, and removes any source routing options from outgoing packets. This attribute only applies to AIX 4.2.1 or later.

ip6_defttl**Purpose:**

Specifies the default hop count that is used for Internet Protocol Version 6 (IPv6) packets if no other hop count is specified.

Values:

Default: 64

Display:

no -a or **no -o ip6_defttl**

Change:

no -o ip6_defttl=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

ip6_prune**Purpose:**

Specifies how often to check the IPv6 routing table for expired routes in seconds.

Values:

Default: 2

Display:

no -a or **no -o ip6_prune**

Change:

no -o ip6_prune=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

ip6forwarding**Purpose:**

Specifies whether the kernel should forward IPv6 packets.

Values:

Default: 0; Range: 0 or 1

Display:

no -a or **no -o ip6forwarding**

Change:

no -o ip6forwarding=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The default value of 0 prevents forwarding of IPv6 packets when they are not for the local systems. A value of 1 enables forwarding. This is a run-time attribute.

ip6srcrouteforward**Purpose:**

Specifies whether the system forwards source-routed IPv6 packets.

Values:

Default: 1; Range: 0 or 1

Display:

no -a or **no -o ip6srcrouteforward**

Change:

no -o ip6srcrouteforward=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The default value of 1 allows the forwarding of source-routed packets. A value of 0 causes all source-routed packets that are not at their destinations to be discarded.

llsleep_timeout**Purpose:**

Specifies timeout value in seconds for link local timeouts (used when **multi_homed=1**)

Values:

Default: 3; Range: Postive values

Display:

no -a or **no -o llsleep_timeout**

Change:

no -o llsleep_timeout=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

main_if6**Purpose:**

Specifies the interface to use for link local addresses. This is only used by **autoconf6** to set up initial routes.

Values:

Default: 0

Display:

no -a or **no -o main_if6**

Change:

no -o main_if6=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

main_site6**Purpose:**

Specifies the interface to use for site local address routing. This is only used if **multi_homed** is set to 3.

Values:

Default: 0

Display:

no -a or **no -o main_site6**

Change:

no -o main_site6=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

maxmbuf**Purpose:**

Maximum Kbytes of real memory allowed for MBUFS.

Values:

Default: 0, Range: x to y

Display:

lsattr -E -l sys0 -a maxmbuf

Change:

chdev -l sys0 -a maxmbuf=*NewValue*

Change is effective immediately and is permanent. If the **-T** flag is used, the change is immediate and lasts until the next boot. If the **-P** flag is used, the change is deferred until the next boot and is permanent.

Diagnosis:

N/A

Tuning:

In AIX 4.2 and later, if **maxmbuf** is greater than 0, the **maxmbuf** value is used regardless of the value of **thewall**. Prior to AIX 4.2, the upper limit on mbufs is the higher value of **maxmbuf** or **thewall**.

Refer to:

Tuning Network Memory

maxnip6q**Purpose:**

Specifies the maximum number of IPv6 packet-reassembly queues.

Values:

Default: 20

Display:

no -a or **no -o maxnip6q**

Change:

no -o maxnip6q=*NewValue*

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

maxttl**Purpose:**

Specifies the time to live for Routing Information Protocol (RIP) packets in seconds.

Values:

Default: 255

Display:

no -a or **no -o maxttl**

Change:

no -o maxttl=*NewValue*

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a run-time attribute.

MTU**Purpose:**

Limits the size of packets that are transmitted on the network.

Values:

Default: configuration-dependent

Display:

lsattr -E -l interface_name

Change:

chdev -l interface_name -a mtu=NewValue

With the **chdev** command, the interface cannot be changed while it is in use. Change is effective across reboots.

An alternate method is as follows:

ifconfig interface_name mtu NewValue

This changes the MTU size on a running system, but will not preserve the value across a system reboot.

Diagnosis:

Packet fragmentation statistics.

Tuning:

Increase MTU size for the network interfaces. For the Gigabit Ethernet adapter use the device attribute **jumbo_frames=yes** to enable jumbo frames (just setting MTU to 9000 on the interface is not enough).

Refer to:

UDP and TCP/IP Performance Overview and Tuning TCP and UDP Performance

multi_homed**Purpose:**

Specifies the level of multi-homed IPv6 host support.

Values:

Default: 1; Range: 0, 1, 2, 3

Display:

no -a or **no -o multi_homed**

Change:

no -o multi_homed=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This will only be performed for connections whose destination port is specified in the list of the **delayackports** attribute. This can be used to increase performance when communicating with an HTTP server. The attribute can have one of four values:

0 - Indicates the original functionality in AIX 4.3.

1 - Indicates that link local addresses will be resolved by querying each interface for the link local address.

2 - Indicates that link local addresses will only be examined for the interface defined by **main_if6**.

3 - Indicates that link local addresses will only be examined for the interface defined by **main_if6**, and site local addresses will only be routed for the **main_site6** interface.

nbc_limit

Purpose:

Specifies the total maximum amount of memory that can be used for the Network Buffer Cache (NBC) in Kbytes.

Values:

Default: derived from **thewall**

Display:

no -a or **no -o nbc_limit**

Change:

no -o nbc_limit=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

When the cache grows to this limit, the least-used caches are flushed out of cache to make room for the new ones. This attribute only applies to AIX 4.3.2 or later. NBC is only used by the **send_file()** API and some Web servers that use the get engine in the kernel.

nbc_max_cache

Purpose:

Specifies the maximum size of the cache object allowed in the Network Buffer Cache (NBC) in bytes.

Values:

Default: 131072 (128K)

Display:

no -a or **no -o nbc_max_cache**

Change:

no -o no -o nbc_max_cache=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

Data object bigger than this size is not be put in the NBC. This attribute only applies to AIX 4.3.2 or later. NBC is only used by the **send_file()** API and some Web servers that use the get engine in the kernel.

nbc_min_cache

Purpose:

Specifies the minimum size of the cache object allowed in the Network Buffer Cache (NBC) in bytes.

Values:

Default: 1 byte

Display:

no -a or **no -o nbc_min_cache**

Change:

no -o nbc_min_cache=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

Data object smaller than this size is not be put in the NBC. This attribute only applies to Version 4.3.2 or later. NBC is only used by the **send_file()** API and some Web servers that use the get engine in the kernel.

nbc_pseg (AIX 4.3.3 and later)**Purpose:**

Specifies the maximum number of private segments that can be created for the Network Buffer Cache (NBC).

Values:

Default: 0

Display:

no -a or **no -o nbc_pseg**

Change:

no -o nbc_pseg=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

When this option is set to a nonzero value, data objects with size between the size specified in **nbc_max_cache** and the segment size (256 MB) will be cached in a private segment. Data objects bigger than the segment size will not be cached at all. When this many private segments exist in NBC, cache data in private segments may be flushed for new cache data so the number of private segments will not exceed the limit. When this option is set to 0, all cache in private segments will be flushed.

nbc_pseg_limit (AIX 4.3.3 and later)**Purpose:**

Specifies the maximum total cached data size (KB) allowed in private segments in the Network Buffer Cache (NBC).

Values:

Default: 1/2 of RAM

Display:

no -a or **no -o nbc_pseg_limit**

Change:

no -o nbc_pseg_limit=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

Because data cached in private segments will be pinned by the Network Buffer Cache, this option

provides a control on the amount of pinned memory used for Network Buffer Cache in addition to the network buffers in global segments. When this limit is met, cache data in private segments may be flushed for new cache data so the total pinned memory size will not exceed the limit. When this option is set to 0, all cache in private segments will be flushed.

ndpqsize

Purpose:

Specifies the number of packets to hold waiting on completion of a Neighbor Discovery Protocol (NDP) entry (used by MTU Path Discovery).

Values:

Default: 50

Display:

no -a or **no -o ndpqsize**

Change:

no -o ndpqsize=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

ndpt_down

Purpose:

Specifies the time, in half-seconds, to hold down a Neighbor Discovery Protocol (NDP) entry.

Values:

Default: 3 (1.5 seconds)

Display:

no -a or **no -o ndpt_down**

Change:

no -o ndpt_down=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

ndpt_keep

Purpose:

Specifies the time, in half seconds, to keep a Neighbor Discovery Protocol (NDP) entry.

Values:

Default: 120 (60 seconds)

Display:

no -a or **no -o ndpt_keep**

Change:

no -o ndpt_keep=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

ndpt_mmaxtries**Purpose:**

Specifies the maximum number of Multicast NDP packets to send.

Values:

Default: 3

Display:**no -a** or **no -o ndpt_mmaxtries****Change:****no -o no -o ndpt_mmaxtries=NewValue**Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.**Diagnosis:**

N/A

Tuning:

N/A

ndpt_probe**Purpose:**

Specifies the time, in half-seconds, to delay before sending the first Neighbor Discovery Protocol (NDP) probe.

Values:

Default: 5 (2.5 seconds)

Display:**no -a** or **no -o ndpt_probe****Change:****no -o ndpt_probe=NewValue**Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.**Diagnosis:**

N/A

Tuning:

N/A

ndpt_reachable**Purpose:**

Specifies the time, in half-seconds, to test if a Neighbor Discovery Protocol (NDP) entry is still valid.

Values:

Default: 30 (15 seconds)

Display:**no -a** or **no -o ndpt_reachable**

Change:

no -o ndpt_reachable=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

ndpt_retrans**Purpose:**

Specifies the time, in half-seconds, to wait before retransmitting a Neighbor Discovery Protocol (NDP) request.

Values:

Default: 1 (half second)

Display:

no -a or **no -o ndpt_retrans**

Change:

no -o ndpt_retrans=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

ndpt_umaxtries**Purpose:**

Specifies the maximum number of Unicast NDP packets to send.

Values:

Default: 3

Display:

no -a or **no -o ndpt_umaxtries**

Change:

no -o ndpt_umaxtries=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

net_malloc_police**Purpose:**

Specifies the size of the net_malloc and net_free trace buffers.

Values:

Default: 0

Display:

no -a or **no -o net_malloc_police**

Change:

no -o net_malloc_police=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

If the value of this variable is non-zero, all `net_malloc` and `net_free` buffers will be traced in a kernel buffer and by system trace hook `HKWD_NET_MALLOC`. Additional error-checking will also be enabled. This includes checks for freeing a free buffer, alignment, and buffer overwrite. Enable this attribute only when investigating some network problem, because performance is affected negatively when turned on.

The default value is zero (policing off). Values of **net_malloc_police** larger than 1024 will allocate that many items in the kernel buffer for tracing. This is a run-time attribute.

Refer to:

The netstat Command

nonlocsrcroute**Purpose:**

Tells the Internet Protocol that strictly source-routed packets may be addressed to hosts outside the local network.

Values:

Default: 0; Range: 0 to 1

Display:

no -a or **no -o nonlocsrcroute**

Change:

no -o nonlocsrcroute=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

A default value of 0 disallows addressing to outside hosts. The value of 1 allows packets to be addressed to outside hosts. Loosely source-routed packets are not affected by this attribute. This is a configuration decision with minimal performance consequences. This is a run-time attribute.

pmtu_default_age**Purpose:**

Specifies the default amount of time (in minutes) before the path MTU value for UDP paths is checked for a lower value.

Values:

Default: 10

Display:

no -a or **no -o pmtu_default_age**

Change:

no -o pmtu_default_age=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

A value of zero allows no aging. The default value is 10 minutes. The **pmtu_default_age** value can be overridden by UDP applications. This attribute only applies to AIX 4.2.1 or later. This is a run-time attribute.

pmtu_rediscover_interval**Purpose:**

Specifies the default amount of time (in minutes) before the path MTU value for UDP and TCP paths are checked for a higher value.

Values:

Default: 30

Display:

no -a or **no -o pmtu_rediscover_interval**

Change:

no -o pmtu_rediscover_interval=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

A value of 0 allows no path MTU rediscovery. The default value is 30 minutes. This attribute only applies to AIX 4.2.1 or later. This is a run-time attribute.

rec_que_size**Purpose:**

Specifies the maximum number of receive buffers that can be queued up for the interface.

Values:

Default: configuration-dependent

Display:

lsattr -E -l interface_name

Change:

ifconfig interface_name detach

chdev -l interface_name -a rec_que_size=NewValue

ifconfig interface_name hostname up

Cannot be changed while the interface is in use. Change is effective across boots.

Diagnosis:

N/A

Tuning:

Increase size.

Refer to:

Adapter Transmit and Receive Queue Tuning

rfc1122addrchk

Purpose:

Performs address validation as specified by RFC1122 (Requirements for Internet Hosts-Communication Layers).

Values:

Default: 0; Range 0 to 1

Display:

no -a or **no -o rfc1122addrchk**

Change:

no -o rfc1122addrchk=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The default value of 0 does not perform address validation. A value of 1 performs address validation. This is a run-time attribute.

rfc1323

Purpose:

Enables TCP enhancements as specified by RFC 1323 (TCP Extensions for High Performance). Value of 1 indicates that **tcp_sendspace** and **tcp_recvspace** can exceed 64 KB.

Values:

Default: 0; Range 0 to 1

Display:

no -a or **no -o rfc1323**

ISNO: **Isattr -EI interface** or **ifconfig interface**

Change:

no -o rfc1323=NewValue

Change takes effect immediately only for new TCP connections (not existing connections). Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

ISNO: **ifconfig interface rfc1323 NewValue**

OR

chdev -l interface -a rfc1323=NewValue

The **ifconfig** command sets values temporarily, making it useful for testing. The **chdev** command alters the ODM, so custom values return after system reboots.

Diagnosis:

N/A

Tuning:

The default value of 0 disables the RFC enhancements on a systemwide scale. A value of 1 specifies that all TCP connections will attempt to negotiate the RFC enhancements. The SOCKETS application can override the default behavior on individual TCP connections, using the **setsockopt()** subroutine. This is a run-time attribute. Make changes before attempting to set **tcp_sendspace** and **tcp_recvspace** to more than 64 KB.

Refer to:

TCP Socket Buffer Tuning

route_expire

Purpose:

Specifies whether the route expires.

Values:

Default: 0; Range 0 to 1

Display:

no -a or **no -o route_expire**

Change:

no -o route_expire=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

A value of 0 allows no route expiration, which is the default. Negative values are not allowed for this option. This attribute only applies to Version 4.2.1 or later. This is a run-time attribute.

Refer to:

Tuning TCP Maximum Segment Size

routerevalidate

Purpose:

Specifies that each connection's cached route should be revalidated each time a new route is added to the routing table. This will ensure that applications that keep the same connection open for long periods of time (for example, NFS) use the correct route after routing-table changes occur.

Values:

Default: 0; Range 0 to 1

Display:

no -a or **no -o routerevalidate**

Change:

no -o routerevalidate=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

If there is communication loss between HACMP nodes or between NFS client and server, routes may have been changed but the values in the cache are being used.

Tuning:

The default value of 0 does not revalidate the cached routes. Turning on this option may cause some performance degradation. Value should be set to 1 for HACMP. This is a run-time attribute.

rto_high

Purpose:

Specifies the TCP Retransmit timeout high value used in calculating factors and the maximum retransmittals allowable used in TCP data segment retransmittals.

Values:

Default: 64

Display:

no -a or **no -o rto_high**

Change:

no -o rto_high=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The **rto_high** attribute is the high factor. This is a load-time attribute.

rto_length**Purpose:**

Specifies the TCP Retransmit timeout length value used in calculating factors and the maximum retransmittals allowable used in TCP data segment retransmittals.

Values:

Default: 13

Display:

no -a or **no -o rto_length**

Change:

no -o rto_length=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The **rto_length** attribute is the total number of time segments. This is a load-time attribute.

rto_limit**Purpose:**

Specifies the TCP Retransmit timeout limit value used in calculating factors and the maximum retransmittals allowable used in TCP data segment retransmittals.

Values:

Default: 7

Display:

no -a or **no -o rto_limit**

Change:

no -o rto_limit=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The **rto_limit** attribute is the number of time segments from **rto_low** to **rto_high**. This is a load-time attribute.

rto_low**Purpose:**

Specifies the TCP Retransmit timeout low value used in calculating factors and the maximum retransmittals allowable used in TCP data segment retransmittals.

Values:

Default: 1

Display:

no -a or **no -o rto_low**

Change:

no -o rto_low=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The `rto_low` attribute is the low factor. This is a load-time attribute.

sack (AIX 4.3.3 and later)**Purpose:**

Specifies if Selective Acknowledgment is on.

Values:

Default: 0 (off); Range: 0 or 1

Display:

no -a or **no -o sack**

Change:

no -o sack=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

Normal TCP has to retransmit all packets after a dropped packet. With large window sizes, this can result in lost performance if many packets are dropped. Selective Ack enables code to selectively retransmit the lost packet(s). If there are a lot of retransmits of fragments and the receive buffer sizes are large, then it might be beneficial to turn this attribute on. This is a TCP negotiated option, so it must be supported on both endpoints before it will be used.

sb_max**Purpose:**

Specifies the maximum buffer size allowed for a TCP and UDP socket. Limits **setsockopt()**, **udp_sendspace**, **udp_recvspace**, **tcp_sendspace**, and **tcp_recvspace**.

Values:

Default: 1048576 bytes

Display:

no -a or **no -o sb_max**

Change:

no -o sb_max=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

Increase size, preferably to multiple of 4096. Should be approximately two to four times the largest socket buffer limit. This is a run-time attribute.

Refer to:

TCP Socket Buffer Tuning and Tuning Other Layers to Improve NFS Performance

send_file_duration**Purpose:**

Specifies the cache validation duration for all the file objects that the system call **send_file()** accessed in the Network Buffer Cache (in seconds).

Values:

Default: 300 (5 minutes)

Display:

no -a or **no -o send_file_duration**

Change:

no -o send_file_duration=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

A value of 0 means that the cache will be validated for every access. This attribute only applies to AIX 4.3.2 or later.

site6_index**Purpose:**

Specifies the maximum interface number for site local routing.

Values:

Default: 0

Display:

no -a or **no -o site6_index**

Change:

no -o site6_index=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

sockthresh**Purpose:**

Specifies the maximum amount of network memory that can be allocated for sockets. Used to prevent new sockets or TCP connections from exhausting all MBUF memory and reserve the remaining memory for the existing sockets or TCP connections.

Values:

Default: 85 percent

Display:

no -a or **no -o sockthresh**

Change:

no -o sockthresh=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

When the total amount of memory allocated by the **net_malloc()** subroutine reaches this threshold, the **socket()** and **socketpair()** system calls fail with an error of ENOBUFS. Incoming connection requests are silently discarded. Existing sockets can continue to use additional memory. The **sockthresh** attribute represents a percentage of the **thewall** attribute, with possible values of 1 to 100 and a default of 85. This is a run-time attribute. This attribute only applies to AIX 4.3.1 or later.

Refer to:

Socket Layer

somaxconn**Purpose:**

Specifies the maximum listen backlog.

Values:

Default: 1024 connections

Display:

no -a or **no -o somaxconn**

Change:

no -o somaxconn=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a run-time attribute. This attribute only applies to Versions 4.1.5, 4.2 or later. Increase on busy Web servers to handle peak connection rates.

subnetsarelocal**Purpose:**

Specifies whether all subnets that match the subnet mask are to be considered local for purposes of establishing, for example, the TCP maximum segment size.

Values:

Default: 1 (yes); Range: 0 to 1

Display:

no -a or **no -o subnetsarelocal**

Change:

no -o subnetsarelocal=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This attribute is used by the **in_localaddress()** subroutine. The default value of 1 specifies that addresses that match the local network mask are local. If the value is 0, only addresses matching the local subnetwork are local.

This is a configuration decision with performance consequences. If the subnets do not all have the same MTU, fragmentation at bridges may degrade performance. If the subnets do have the same MTU, and **subnetsarelocal** is 0, TCP sessions may use an unnecessarily small MSS. This is a run-time attribute.

Refer to:

Tuning TCP Maximum Segment Size

tcp_ephemeral_high**Purpose:**

Specifies the largest port number to allocate for TCP ephemeral ports.

Values:

Default: 65535; Range: 16384 to 65535

Display:

no -a or **no -o tcp_ephemeral_high**

Change:

no -o tcp_ephemeral_high=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The number of ephemeral sockets is determined by **tcp_ephemeral_high** minus **tcp_ephemeral_low**. For maximum number of ephemeral sockets, set **tcp_ephemeral_high** to 65535 and **tcp_ephemeral_low** to 1024.

Refer to:

Socket Layer

tcp_ephemeral_low**Purpose:**

Specifies the smallest port number to allocate for TCP ephemeral ports.

Values:

Default: 32768; Range: 1024 to **tcp_ephemeral_high-1**

Display:

no -a or **no -o tcp_ephemeral_low**

Change:

no -o tcp_ephemeral_low=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The number of ephemeral sockets is determined by **tcp_ephemeral_high** minus **tcp_ephemeral_low**. For maximum number of ephemeral sockets, set **tcp_ephemeral_high** to 65535 and **tcp_ephemeral_low** to 1024.

Refer to:
Socket Layer

tcp_keepidle

Purpose:
Specifies the length of time to keep an idle TCP connection active, measured in half-seconds.

Values:
Default: 14400 (2 hours)

Display:
no -a or **no -o tcp_keepidle**

Change:
no -o tcp_keepidle=NewValue
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:
N/A

Tuning:
This is a configuration decision with minimal performance consequences. No change is recommended. This is a run-time attribute.

tcp_keepinit

Purpose:
Sets the initial timeout value for a TCP connection in half-seconds.

Values:
Default: 150 (75 seconds)

Display:
no -a or **no -o tcp_keepinit**

Change:
no -o tcp_keepinit=NewValue
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:
N/A

Tuning:
This is a run-time attribute.

tcp_keepintvl

Purpose:
Specifies the interval, measured in half-seconds, between packets sent to validate the TCP connection.

Values:
Default: 150 (75 seconds)

Display:
no -a or **no -o tcp_keepintvl**

Change:
no -o tcp_keepintvl=NewValue
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a configuration decision with minimal performance consequences. No change is recommended. If the interval were shortened significantly, processing and bandwidth costs might become significant. This is a run-time attribute.

tcp_mssdflt**Purpose:**

Default maximum segment size used in communicating with remote networks.

Values:

Default: 512 bytes

Display:

no -a or **no -o tcp_mssdflt**

ISNO: **lsattr -El interface** or **ifconfig interface**

Change:

no -o =NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

ISNO: **ifconfig interface tcp_mssdflt NewValue**

OR

chdev -l interface -a tcp_mssdflt=NewValue

The **ifconfig** command sets values temporarily, making it useful for testing. The **chdev** command alters the ODM, so custom values return after system reboots.

Diagnosis:

N/A

Tuning:

For AIX 4.2.1 or later, **tcp_mssdflt** is only used if path MTU discovery is not enabled or path MTU discovery fails to discover a path MTU. Limiting data to (MTU - 52) bytes ensures that, where possible, only full packets will be sent. This is a run-time attribute.

Refer to:

Tuning TCP Maximum Segment Size

tcp_ndebug**Purpose:**

Specifies the number of **tcp_debug** structures.

Values:

Default: 100

Display:

no -a or **no -o tcp_ndebug**

Change:

no -o tcp_ndebug=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a run-time attribute.

tcp_nodelay

Purpose:

Specifies that sockets using TCP over this interface follow the Nagle algorithm when sending data. By default, TCP follows the Nagle algorithm.

Values:

Default: 0; Range: 0 or 1

Display:

lsattr -El interface or **ifconfig interface**

Change:

ifconfig interface tcp_nodelay NewValue

OR

chdev -l interface -a tcp_nodelay=NewValue

The **ifconfig** command sets values temporarily, making it useful for testing. The **chdev** command alters the ODM, so custom values return after system reboots.

Diagnosis:

N/A

Tuning:

This is an Interface-Specific Network Option (ISNO) option.

Refer to:

Relative Level of Function in UDP and TCP and Interface-Specific Network Options (ISNO)

tcp_pmtu_discover

Purpose:

Enables or disables path MTU discovery for TCP applications.

Values:

Default: 0, in AIX 4.3.3 it is 1

Display:

no -a or **no -o tcp_pmtu_discover**

Change:

no -o tcp_pmtu_discover=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

A value of 0 disables path MTU discovery for TCP applications, while a value of 1 enables it. This attribute only applies to AIX 4.2.1 or later. This is a run-time attribute.

Refer to:

Tuning TCP Maximum Segment Size

tcp_recvspace

Purpose:

Specifies the system default socket buffer size for receiving data. This affects the window size used by TCP.

Values:

Default: 4096 bytes (16384 set by **/etc/rc.net**)

Display:

no -a or **no -o tcp_recvspace**
ISNO: **lsattr -El interface** or **ifconfig interface**

Change:

no -o tcp_recvspace=NewValue
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

ISNO: **ifconfig interface tcp_recvspace NewValue**
OR

chdev -l interface -a tcp_recvspace=NewValue
The **ifconfig** command sets values temporarily, making it useful for testing. The **chdev** command alters the ODM, so custom values return after system reboots.

Diagnosis:

N/A

Tuning:

Setting the socket buffer size to 16 KB (16,384) improves performance over standard Ethernet and Token-Ring networks. The default is a value of 4096. However, a value of 16,384 is set automatically by the **rc.net** file or the **rc.bsdnet** file (if Berkeley-style configuration is issued).

Lower bandwidth networks, such as Serial Line Internet Protocol (SLIP), or higher bandwidth networks, such as Serial Optical Link, should have different optimum buffer sizes. The optimum buffer size is the product of the media bandwidth and the average round-trip time of a packet.

The **tcp_recvspace** attribute must specify a socket buffer size less than or equal to the setting of the **sb_max** attribute. This is a run-time attribute, but for daemons started by the **inetd** daemon, run the following commands: **stopsrc -s inetd ; startsrc -s inetd**

Refer to:

TCP Socket Buffer Tuning

tcp_sendspace**Purpose:**

Specifies the system default socket buffer size for sending data.

Values:

Default: 4096 bytes (16384 set **/etc/rc.net**)

Display:

no -a or **no -o tcp_sendspace**
ISNO: **lsattr -El interface** or **ifconfig interface**

Change:

no -o tcp_sendspace=NewValue
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

ISNO: **ifconfig interface tcp_sendspace NewValue**
OR

chdev -l interface -a tcp_sendspace=NewValue
The **ifconfig** command sets values temporarily, making it useful for testing. The **chdev** command alters the ODM, so custom values return after system reboots.

Diagnosis:

N/A

Tuning:

This affects the window size used by TCP. Setting the socket buffer size to 16 KB (16,384) improves performance over standard Ethernet and Token-Ring networks. The default is a value of 4096; however, a value of 16,384 is set automatically by the **rc.net** file or the **rc.bsddnet** file (if Berkeley-style configuration is issued).

Lower bandwidth networks, such as Serial Line Internet Protocol (SLIP), or higher bandwidth networks, such as Serial Optical Link, should have different optimum buffer sizes. The optimum buffer size is the product of the media bandwidth and the average round-trip time of a packet:

$$\text{optimum_window} = \text{bandwidth} * \text{average_round_trip_time}$$

The **tcp_sendspace** attribute must specify a socket buffer size less than or equal to the setting of the **sb_max** attribute. The **tcp_sendspace** parameter is a run-time attribute, but for daemons started by the **inetd** daemon, run the following commands: **stopsrc -s inetd ; startsrc -s inetd**

Refer to:

TCP Socket Buffer Tuning

tcp_timewait**Purpose:**

The **tcp_timewait** option is used to configure how long connections are kept in the timewait state in 15-second intervals.

Values:

Default: 1; Range: 1 to 5

Display:

no -a or **no -o tcp_timewait**

Change:

no -o tcp_timewait=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

Increasing this value will degrade performance of Web servers or applications that open and close a lot of TCP connections.

tcp_ttl**Purpose:**

Specifies the time to live for TCP packets.

Values:

Default: 60 ticks (100 ticks per minute)

Display:

no -a or **no -o tcp_ttl**

Change:

no -o tcp_ttl=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

netstat -s

Tuning:

If the system is experiencing TCP timeouts, increasing **tcp_ttl** may reduce retransmissions. This is a run-time attribute.

thewall

Purpose:

Specifies the maximum amount of memory, in kilobytes, that is allocated to the memory pool.

Values:

Default: In operating system 4.3.2 and later: 1/2 of RAM or 1 GB (whichever is smaller). Systems that are not Common Hardware Reference Platform (CHRP) are limited to 256 MB.

Display:

no -a or **no -o thewall**

Change:

no -o thewall=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

In AIX 4.2.1. and earlier, the default value is 1/8 of real memory or 65536 (64 megabytes), whichever is smaller. In AIX 4.3, the default value is 1/8 of real memory or 131072 (128 megabytes) whichever is smaller. In AIX 4.3.1 and later, the default value is 1/2 of real memory or 131072 (128 megabytes) whichever is smaller. This is a run-time attribute.

Refer to:

Tuning mbuf Pool Performance

threads

Purpose:

Enabling the dog threads feature will allow interface drivers to queue the incoming packet to a thread and the thread will handle calling IP, TCP, and the socket code.

Values:

Default: Not set

Display:

N/A

Change:

ifconfig interface_name thread or
ifconfig interface_name hostname up thread

Change takes effect immediately. Change is effective until next boot.

Diagnosis:

N/A

Tuning:

This feature is most likely to improve performance when there is high input packet rate and more CPUs than adapters.

Refer to:

Adapter Transmit and Receive Queue Tuning

udp_ephemeral_high

Purpose:

Specifies the largest port number to allocate for UDP ephemeral ports.

Values:

Default: 65535

Display:

no -a or **no -o udp_etherminal_high**

Change:

no -o udp_etherminal_high=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

Refer to:

Socket Layer

udp_etherminal_low**Purpose:**

Specifies the smallest port number to allocate for UDP etherminal ports.

Values:

Default: 32768

Display:

no -a or **no -o udp_etherminal_low**

Change:

no -o udp_etherminal_low=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

Refer to:

Socket Layer

udp_pmtu_discover**Purpose:**

Enables or disables path MTU discovery for UDP applications.

Values:

Default: 0, in AIX 4.3.3 it is 1

Display:

no -a or **no -o udp_pmtu_discover**

Change:

no -o udp_pmtu_discover=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

UDP applications must be specifically written to use path MTU discovery. A value of 0 disables the feature, while a value of 1 enables it. The default value is 0. This attribute only applies to AIX 4.2.1 or later. This is a run-time attribute.

udp_recvspace

Purpose:

Specifies the system default socket-buffer size for receiving UDP data.

Values:

Default: 41600 bytes

Display:

no -a or **no -o udp_recvspace**

Change:

no -o udp_recvspace=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

Nonzero *n* in **netstat -s** report of udp: *n* socket buffer overflows

Tuning:

The **udp_recvspace** attribute must specify a socket buffer size less than or equal to the setting of the **sb_max** attribute. Increase size, preferably to multiple of 4096. This is a run-time attribute.

Refer to:

UDP Socket Buffer Tuning

udp_sendspace

Purpose:

Specifies the system default socket-buffer size for sending UDP data.

Values:

Default: 9216 bytes

Display:

no -a or **no -o udp_sendspace**

Change:

no -o udp_sendspace=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The **udp_sendspace** attribute must specify a socket buffer size less than or equal to the setting of the **sb_max** attribute. Increase size, preferably to multiple of 4096. This is a run-time attribute.

Refer to:

UDP Socket Buffer Tuning

udp_ttl

Purpose:

Specifies the time to live for UDP packets.

Values:

Default: 30 seconds

Display:

no -a or **no -o udp_ttl**

Change:

no -o udp_ttl=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a run-time attribute.

udpcksum**Purpose:**

Allows UDP checksum to be turned on/off.

Values:

Default: 1

Display:

no -a or **no -o udpcksum**

Change:

no -o udpcksum=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

A value of 0 turns it off; while a value of 1 turns it on. This is a run-time attribute.

use_isno (AIX 4.3.3 and later)**Purpose:**

Allows per interface tuning options.

Values:

Default: 1 (on); Range: 0 or 1

Display:

no -a or **no -o use_isno**

Change:

no -o use_isno=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

A value of 1 means it is on, 0 is off. If the TCP tunable parameters per interface (tunable through SMIT or the **chdev** command) have been set, they will override the TCP global values if **use_isno** is set to 1. Application can still override all of these with the **setsockopt()** subroutine.

Refer to:

Interface-Specific Network Options (ISNO)

xmt_que_size**Purpose:**

Specifies the maximum number of send buffers that can be queued up for the interface.

Values:

Default: configuration-dependent

Display:

lsattr -E -l interface_name

Change:

ifconfig interface_name detach
chdev -l interface_name -aque_size_name=NewValue
ifconfig interface_name hostname up

Cannot be changed while the interface is in use. Change is effective across reboots.

Diagnosis:

netstat -i (0err > 0)

Tuning:

Increase size.

Refer to:

The netstat Command

NFS Option Tunable Parameters

biod Count

Purpose:

Number of biod processes available to handle NFS requests on a client.

Values:

Default: 6; Range: 1 to any positive integer

Display:

ps -efa | grep biod

Change:

chnfs -b NewValue
Change normally takes effect immediately and is permanent. The **-N** flag causes an immediate, temporary change. The **-I** flag causes a change that takes effect at the next boot.

Diagnosis:

netstat -s to look for UDP socket buffer overflows.

Tuning:

Increase number until socket buffer overflows cease.

Refer to:

How Many biod and nfsd Daemons Are Needed?

nfs_allow_all_signals

Purpose:

Specifies that the NFS server adhere to signal handling requirements for blocked locks for the UNIX 95/98 test suites.

Values:

Default: 0; Range: 0 to 1

Display:

nfsd -a or **nfsd -o nfs_allow_all_signals**

Change:

nfsd -o nfs_allow_all_signals=NewValue
Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfsd** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

A value of 1 turns `nfs_allow_all_signals` on, and a value of 0 turns it off.

nfs_device_specific_bufs (AIX 4.2.1 and later)**Purpose:**

This option allows the NFS server to use memory allocations from network devices if the network device supports such a feature.

Values:

Default: 1; Range: 0 or 1

Display:

`nfsd -a` or `nfsd -o nfs_device_specific_bufs`

Change:

`nfsd -o nfs_device_specific_bufs=NewValue`

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding `nfsd` command to `/etc/rc.nfs`.

Diagnosis:

N/A

Tuning:

Use of these special memory allocations by the NFS server can positively affect the overall performance of the NFS server. The default of 1 means the NFS server is allowed to use the special network device memory allocations. If the value of 0 is used, the NFS server will use the traditional memory allocations for its processing of NFS client requests. These are buffers managed by a network interface that result in improved performance (over regular mbufs) because no setup for DMA is required on these. Two adapters that support this include the Micro Channel ATM adapter and the SP2 switch adapter.

nfs_duplicate_cache_size (AIX 4.1, Version 4.2.0)**Purpose:**

Sets the size of the NFS RPC duplicate cache on the server.

Values:

Default: 1000; Range: 1 to 10000

Display:

`nfsd -a` or `nfsd -o nfs_duplicate_cache_size`

Change:

`nfsd -o nfs_duplicate_cache_size=NewValue`

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding `nfsd` command to `/etc/rc.nfs`.

Diagnosis:

N/A

Tuning:

The duplicate cache size cannot be decreased. The duplicate cache size should be increased for servers that have a high throughput capability. The duplicate cache is used to allow the server to correctly respond to NFS client retransmissions. If the server flushes this cache before the client is able to retransmit, then the server may respond incorrectly. Therefore, if the server can process 1000 operations before a client retransmits, then the duplicate cache size will need to be increased.

Calculate the number of NFS operations that are being received per second at the NFS server and multiply this by 4. This will produce a duplicate cache size that should be sufficient to allow correct response from the NFS server. The operations that are affected by the duplicate cache are the following: **setattr()**, **write()**, **create()**, **remove()**, **rename()**, **link()**, **symlink()**, **mkdir()**, **rmdir()**.

nfs_dynamic_retrans (AIX 4.1 and later)

Purpose:

Specifies whether the NFS client should use a dynamic retransmission algorithm to decide when to resend NFS requests to the server.

Values:

Default: 1; Range: 0 or 1

Display:

nfs -a or **nfs -o nfs_dynamic_retrans**

Change:

nfs -o nfs_dynamic_retrans=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfs** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

If this function is turned on, the **timeo** parameter is only used in the first retransmission. With this parameter set to 1, the NFS client will attempt to adjust its timeout behavior based on past NFS server response.

This allows for a floating timeout value along with adjusting the transfer sizes used. All of this is done based on an accumulative history of the NFS server's response time. In most cases, this parameter does not need to be adjusted. There are some instances where the straightforward timeout behavior is desired for the NFS client. In these cases, the value should be set to 0 before mounting file systems.

Refer to:

Tuning to Avoid Retransmits

nfs_gather_threshold

Purpose:

Sets the minimum size of write requests for which write gathering is done.

Values:

Default: 4096; Useful Range: 512 to 8193

Display:

nfs -a or **nfs -o nfs_gather_threshold**

Change:

nfs -o nfs_gather_threshold=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfs** command to **/etc/rc.nfs**.

Tuning:

One of the following two situations exists:

(1) Delays are observed in responding to RPC requests, particularly those where the client is exclusively doing non-sequential writes or the files being written are being written with file locks held on the client.

(2) Clients are writing with write sizes < 4096 and write-gather is not working. If write-gather is to

be disabled, change the **nfs_gather_threshold** to a value greater than the largest possible write. For AIX Version 4 running NFS Version 2, this value is 8192. Changing the value to 8193 disables write gather. Use this for the situation described above in scenario (1). If write gather is being bypassed due to a small write size, say 1024, change the write gather parameter to gather smaller writes; for example, set to 1024.

nfs_iopace_pages (AIX 4.1)

Purpose:

Specifies the number of NFS file pages that are scheduled to be written back to the server through the VMM at one time. This I/O scheduling control occurs on close of a file and when the system invokes the **syncd** daemon.

Values:

Default: 32 (before AIX 4.2.1); Range: 1 to 65536; Default is 0 in 4.2.1 and later releases

Display:

nfs -a or **nfs** -o **nfs_iopace_pages**

Change:

nfs -o **nfs_iopace_pages=NewValue**

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfs** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

When an application writes a large file to an NFS mounted filesystem, that file data is written to the NFS server when the file is closed. In some cases, the resource it takes to write that file to the server may prevent other NFS file I/O from occurring. This parameter limits the number of 4k pages written to the server to the value of **nfs_iopace_pages**. The NFS client will schedule **nfs_iopace_pages** for writing to the server and then will wait for these to complete before scheduling the next batch of pages. The default value will usually be sufficient for most environments. Decreased the values if there are large amounts of contention for NFS client resources. If there is low contention, the value can be increased. In AIX 4.2.1 and later, if **nfs_iopace_pages=0**, then the number of pages written by the **syncd** daemon at one time is as follows:

$MAX ((filesize/8)-1, 32)$

nfs_max_connections

Purpose:

Specifies the maximum number of TCP connections allowed into the server.

Values:

Default: 0 (indicates no limit)

Display:

nfs -a or **nfs** -o **nfs_max_connections**

Change:

nfs -o **nfs_max_connections=NewValue**

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfs** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

Limits number of connections into the server in order to reduce load.

Refer to:

Tuning Other Layers to Improve NFS Performance

nfs_max_read_size (AIX 4.3.1 and later)**Purpose:**

Allows the system administrator to control the NFS RPC sizes at the server.

Values:

Default: 32678; Range: 512 to 65536

Display:

nfsd -a or **nfsd -o nfs_max_read_size**

Change:

nfsd -o nfs_max_read_size=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfsd** command to **/etc/rc.nfs**.

Diagnosis:

Useful when all clients need to have changes in the read/write sizes, and it is impractical to change the clients.

Tuning:

Default means to use the values used by the client mount. This may be required to reduce the V3 read/write sizes when the mounts cannot be manipulated directly on the clients, in particular during NIM installations on networks where the network is dropping packets with the default 32K read/write sizes. In that case, set the maximum size to a smaller size that works on the network. It can also be useful where network devices are dropping packets and a generic change is desired for communications with the server.

nfs_max_threads (AIX 4.2.1 and later)**Purpose:**

Specifies the maximum number of NFS server threads that are created to service incoming NFS requests.

Values:

Default: 3891; Range: 0 to 3891

Display:

nfsd -a or **nfsd -o nfs_max_threads**

Change:

nfsd -o nfs_max_threads=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfsd** command to **/etc/rc.nfs**.

Diagnosis:

With AIX 4.2.1, the NFS server is multithreaded. The NFS server threads are created as demand increases for the NFS server. When the NFS server threads become idle, they will exit. This allows the server to adapt to the needs of the NFS clients. The **nfs_max_threads** parameter is the maximum number of threads that can be created.

Tuning:

In general, it does not detract from overall system performance to have the maximum set to something very large because the NFS server will create threads as needed. However, this assumes that NFS-serving is the primary machine purpose. If the desire is to share the system with other activities, then the maximum number of threads may need to be set low. The maximum number can also be specified as a parameter to the **nfsd** daemon.

Refer to:

How Many biod and nfsd Daemons Are Needed?

nfs_max_write_size (AIX 4.3.1 and later)**Purpose:**

Allows the system administrator to control the NFS RPC sizes at the server.

Values:

Default: 32678; Range: 512 to 65536

Display:

nfs -a or **nfs** -o **nfs_max_write_size**

Change:

nfs -o **nfs_max_write_size=NewValue**

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfs** command to **/etc/rc.nfs**.

Diagnosis:

Useful when all clients need to have changes in the read/write sizes, and it is impractical to change the clients.

Tuning:

Default means to use the values used by the client mount. This may be required to reduce the V3 read/write sizes when the mounts cannot be manipulated directly on the clients, in particular during NIM installations on networks where the network is dropping packets with the default 32 K read/write sizes. In that case, set the maximum size to a smaller size that works on the network. It can also be useful where network devices are dropping packets and a generic change is desired for communications with the server.

nfs_repeat_messages (AIX Version 4)**Purpose:**

Checks for duplicate NFS messages. This option is used to avoid displaying duplicate NFS messages.

Values:

Default: 1 (yes); Range: 0 to 1

Display:

nfs -a or **nfs** -o **nfs_repeat_messages**

Change:

nfs -o **nfs_repeat_messages=NewValue**

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfs** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

Tuning this parameter does not affect performance.

nfs_rfc1323 (AIX 4.3)**Purpose:**

Enables very large TCP window size negotiation (greater than 65535 bytes) to occur between systems.

Values:

Default: 0; Range: 0 or 1

Display:

nfso -a or **nfso -o nfs_rfc1323**

Change:

nfso -o nfs_rfc1323=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfso** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

If using the TCP transport between NFS client and server, and both systems support it, this allows the systems to negotiate a TCP window size in a way that will allow more data to be 'in-flight' between the client and server. This increases the throughput potential between client and server. Unlike the **rfc1323** option of the **no** command, this only affects NFS and not other applications in the system. Value of 0 means this is disabled, and value of 1 means it is enabled. If the **no** command parameter **rfc1323** is already set, this NFS option does not need to be set.

nfs_server_base_priority (AIX 4.1 and later)**Purpose:**

Sets the base priority of **nfsd** daemons.

Values:

Default: 0 (priority 60); Range: 31 to 126

Display:

nfso -a or **nfso -o nfs_server_base_priority**

Change:

nfso -o nfs_server_base_priority=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfso** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

By default, the **nfsd** daemons run with a floating process priority. Therefore, as they increase their cumulative CPU time, their priority will change. This parameter can be used to set a static parameter for the **nfsd** daemons. The value of 0 represents the floating priority (default). Other values within the acceptable range will be used to set the priority of the **nfsd** daemon when an NFS request is received at the server.

This option can be used if the NFS server is overloading the system (lowering or making the **nfsd** daemon less favored). It can also be used if you want the **nfsd** daemons be one of the most favored processes on the server. Use caution when setting the parameter because it can render the system almost unusable by other processes. This situation can occur if the NFS server is very busy and will essentially lock out other processes from having run time on the server.

nfs_server_cread (AIX 4.2.1 and later)**Purpose:**

This option allows the NFS server to be very aggressive about the reading of a file. The NFS server can only respond to the specific NFS-read request from the NFS client. However, the NFS server can read data in the file which exists immediately after the current read request. This is normally referred to as *read-ahead*. The NFS server does read-ahead by default.

Values:

Default: 1; Range: 0 or 1

Display:

nfs -a or **nfs -o nfs_server_cread**

Change:

nfs -o nfs_server_cread=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfs** command to **/etc/rc.nfs**.

Diagnosis:

May be useful in cases where server memory is low and too much disk-to-memory activity is occurring.

Tuning:

With the **nfs_server_cread** option enabled, the NFS server becomes very aggressive about doing read-ahead for the NFS client. If value is 1, then aggressive read-ahead is done; If value is 0, normal system default read-ahead methods are used.

"Normal" system read-ahead is controlled by VMM. In AIX 4.2.1, the more aggressive top-half JFS read-ahead was introduced. This mechanism is less susceptible to read-ahead breaking down due to out-of-order requests (which are typical in the NFS server case). When the mechanism is activated, it will read an entire cluster (128 KB, the LVM logical track group size).

nfs_setattr_error (AIX 4.2.1 and later)**Purpose:**

When enabled, NFS server ignores *setattr* requests that are not valid.

Values:

Default: 0; Range: 0 or 1; Value of 1 means enabled, 0 means disabled

Display:

nfs -a or **nfs -o nfs_setattr_error**

Change:

nfs -o nfs_setattr_error=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfs** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

This option is provided for certain PC applications. Tuning this parameter does not affect performance.

nfs_socketsize (AIX 4.1 and later)**Purpose:**

Sets the queue size of the NFS server UDP socket.

Values:

Default: 60000; Practical Range: 60000 to 204800

Display:

nfs -a or **nfs -o nfs_socketsize**

Change:

nfs -o nfs_socketsize=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfs** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

Increase the size of the **nfs_socketsize** variable when **netstat** reports packets dropped due to full socket buffers for UDP, and increasing the number of **nfsd** daemons has not helped.

Refer to:

Increasing NFS Socket Buffer Size

nfs_tcp_duplicate_cache_size (AIX 4.2.1 and later)**Purpose:**

Specifies the number of entries to store in the NFS server's duplicate cache for the TCP network transport.

Values:

Default: 1000; Range: 1 to 10000

Display:

nfsso -a or **nfsso -o nfs_tcp_duplicate_cache_size**

Change:

nfsso -o nfs_tcp_duplicate_cache_size=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfsso** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

The duplicate cache size cannot be decreased. Increase the duplicate cache size for servers that have a high throughput capability. The duplicate cache is used to allow the server to correctly respond to NFS client retransmissions. If the server flushes this cache before the client is able to retransmit, then the server may respond incorrectly. Therefore, if the server can process 1000 operations before a client retransmits, the duplicate cache size must be increased.

Calculate the number of NFS operations that are being received per second at the NFS server and multiply this by 4. The result is a duplicate cache size that should be sufficient to allow correct response from the NFS server. The operations that are affected by the duplicate cache are the following: **setattr()**, **write()**, **create()**, **remove()**, **rename()**, **link()**, **symlink()**, **mkdir()**, **rmdir()**.

nfs_tcp_socketsize (AIX 4.2.1 and later)**Purpose:**

Sets the queue size of the NFS server TCP socket. The queue size is specified in number of bytes. The TCP socket is used for receiving the NFS client requests and can be adjusted so that the NFS server is less likely to drop packets under a heavy load. The value of the **nfs_tcp_socketsize** option must be less than the **sb_max** option, which can be manipulated by the **no** command.

Values:

Default: 60000

Display:

nfsso -a or **nfsso -o nfs_tcp_socketsize**

Change:

nfsso -o nfs_tcp_socketsize=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfsso** command to **/etc/rc.nfs**.

Diagnosis:

Packets dropped when examining the output of the command **netstat -s -p tcp**.

Tuning:

This option reserves, but does not allocate, memory for use by the send and receive socket buffers of the socket. Do not set the **nfs_tcp_socketsize** value to less than 60,000. Large or busy servers should have larger values until TCP NFS traffic shows no packets dropped from the output of the **netstat -s -p tcp** command.

Refer to:

Tuning Other Layers to Improve NFS Performance

nfs_udp_duplicate_cache_size (AIX 4.2.1 and later)**Purpose:**

Specifies the number of entries to store in the NFS server's duplicate cache for the UDP network transport.

Values:

Default: 1000; Range: 1 to 10000

Display:

nfsso -a or **nfsso -o nfs_udp_duplicate_cache_size**

Change:

nfsso -o nfs_udp_duplicate_cache_size=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfsso** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

The duplicate cache size cannot be decreased. Increase the duplicate cache size for servers that have a high throughput capability. The duplicate cache is used to allow the server to correctly respond to NFS client retransmissions. If the server flushes this cache before the client is able to retransmit, then the server may respond incorrectly. Therefore, if the server can process 1000 operations before a client retransmits, the duplicate cache size must be increased.

Calculate the number of NFS operations that are being received per second at the NFS server and multiply this by 4. The result is a duplicate cache size that should be sufficient to allow correct response from the NFS server. The operations that are affected by the duplicate cache are the following: **setattr()**, **write()**, **create()**, **remove()**, **rename()**, **link()**, **symlink()**, **mkdir()**, **rmdir()**.

nfs_use_reserved_ports (AIX 4.2.1 and later)**Purpose:**

Specifies using nonreserved IP port number.

Values:

Default: 0; Range: 0 or 1

Display:

nfsso -a or **nfsso -o nfs_use_reserved_ports**

Change:

nfsso -o nfs_use_reserved_ports=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfsso** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

Value of 0 will use nonreserved IP port number when the NFS client communicates with the NFS server.

nsfd Count**Purpose:**

Number of **nsfd** processes available to handle NFS requests on a server.

Values:

Default: 8; Range: 1 to any positive integer

Display:

ps -efa | grep nsfd

Change:

chnfs -n *NewValue*

Change takes effect immediately and is permanent. The **-N** flag causes an immediate, temporary change. The **-I** flag causes a change that takes effect at the next boot.

Diagnosis:

Use **netstat -s** to look for UDP socket buffer overflows.

Tuning:

Increase number until socket buffer overflows cease.

Refer to:

How Many biod and nsfd Daemons Are Needed?

portcheck**Purpose:**

Checks whether an NFS request originated from a privileged port.

Values:

Default: 0; Range: 0 or 1

Display:

nfso -a or **nfso -o portcheck**

Change:

nfso -o portcheck=*NewValue*

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfso** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

Value of 0 disables the port-checking that is done by the NFS server. A value of 1 directs the NFS server to do port checking on the incoming NFS requests. This is a configuration decision with minimal performance consequences.

udpchecksum**Purpose:**

Turns on or off the generation of checksums on NFS UDP packets.

Values:

Default: 1; Range: 0 or 1

Display:

nfso -a or **nfso -o udpchecksum**

Change:

nfs -o **udpchecksum=NewValue**

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **nfs** command to **/etc/rc.nfs**.

Diagnosis:

N/A

Tuning:

Make sure this value is set to on in any network where packet corruption might occur. Slight performance gains can be realized by turning it off, but at the expense of increased chance of data corruption.

Refer to:

Tuning Other Layers to Improve NFS Performance

Streams Tunable Attributes

The following streams tunable attributes only apply for AIX 4.2 or later.

lowthresh

Purpose:

Specifies the maximum number of bytes that can be allocated using the **allocb()** call for the BPRI_LO priority.

Values:

Default: 90 (90 percent of **thewall**)

Display:

no -a or **no -o lowthresh**

Change:

no -o lowthresh=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

When the total amount of memory allocated by the **net_malloc()** call reaches this threshold, then the **allocb()** request for the BPRI_LO priority returns 0. The **lowthresh** attribute represents a percentage of the **thewall** attribute, and you can set its value from 0 to 100. This is a run-time attribute.

medthresh

Purpose:

Specifies the maximum number of bytes that can be allocated using the **allocb()** call for the BPRI_MED priority.

Values:

Default: 95 (95 percent of **thewall**)

Display:

no -a or **no -o medthresh**

Change:

no -o medthresh=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

When the total amount of memory allocated by the **net_malloc()** call reaches this threshold, then the **allocb()** request for the BPRI_MED priority returns 0. The **medthresh** attribute represents a percentage of the **thewall** attribute, and you can set its value from 0 to 100. This is a run-time attribute.

nstrpush**Purpose:**

Specifies the maximum number (should be at least 8) of modules that you can push onto a single stream.

Values:

Default: 8

Display:**no -a** or **no -o nstrpush****Change:****no -o nstrpush=NewValue**

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

This is a load-time attribute.

psebufcalls**Purpose:**

Specifies the maximum number of bufcalls to allocate by streams.

Values:

Default: 20

Display:**no -a** or **no -o psebufcalls****Change:****no -o psebufcalls=NewValue**

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The stream subsystem allocates certain number of bufcall structures at initialization. When the **allocb()** call fails, the user can register their requests for the **bufcall()** call. You cannot lower this value until the system reboots, at which time it returns to its default value. This is a run-time attribute.

psecache**Purpose:**

Controls the number of stream buffers.

Values:

Default: 1

Display:

no -a or **no -o psecache**

Change:

no -o psecache=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

N/A

pseintrstack**Purpose:**

Specifies the maximum size of the interrupt stack allowed by streams while running in the offlevel.

Values:

Default: 0x3000 (decimal 12288)

Display:

no -a or **no -o pseintrstack**

Change:

no -o pseintrstack=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

When a process running other than INTBASE level enters into a stream, it occasionally encounters a stack overflow problem because the interrupt stack size is too small. Setting this attribute correctly reduces the chances of stack overflow problems. This is a load-time attribute.

psetimers**Purpose:**

Specifies the maximum number of timers to allocate by streams.

Values:

Default: 20

Display:

no -a or **no -o psetimers**

Change:

no -o psetimers=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

The stream subsystem allocates a certain number of timer structures at initialization, so that the streams driver or module can register their **timeout()** calls. You cannot lower this value until the system reboots, at which time it returns to its default value. This is a run-time attribute.

strctlsz

Purpose:

Specifies the maximum number of bytes of information that a single system call can pass to a stream to place into the control part of a message (in an M_PROTO or M_PCPROTO block).

Values:

Default: 1024

Display:

no -a or **no -o strctlsz**

Change:

no -o strctlsz=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

A **putmsg()** call with a control part exceeding this size will fail with ERANGE. This is a run-time attribute.

strmsgsz

Purpose:

Specifies the maximum number of bytes of information that a single system call can pass to a stream to place into the data part of a message (in M_DATA blocks).

Values:

Default: 1024

Display:

no -a or **no -o strmsgsz**

Change:

no -o strmsgsz=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

Any **write()** call exceeding this size is broken into multiple messages. A **putmsg()** call with a data part exceeding this size will fail with ERANGE. This is a run-time attribute.

strthresh

Purpose:

Specifies the maximum number of bytes that streams are normally allowed to allocate.

Values:

Default: depends on **thewall**

Display:

no -a or **no -o strthresh**

Change:

no -o strthresh=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

When the threshold is exceeded, it does not allow users without the appropriate privilege to open streams, push modules, or write to streams devices, and returns ENOSR. The threshold applies only to output side and does not affect data coming into the system (for example, the console continues to work correctly). A value of zero means that there is no threshold. The **strthresh** attribute represents a percentage of the **thewall** attribute, and you can set its value from 0 to 100. The **thewall** attribute indicates the maximum number of bytes that can be allocated by streams and sockets using the **net_malloc()** call. When you change **thewall** attribute, the threshold is updated accordingly.

Refer to:

Tuning Network Memory

strturncnt**Purpose:**

Specifies the maximum number of requests handled by the current running thread for Module- or Elsewhere-level streams synchronization.

Values:

Default: 15

Display:

no -a or **no -o strturncnt**

Change:

no -o strturncnt=NewValue

Change takes effect immediately. Change is effective until next boot. Permanent change is made by adding **no** command to **/etc/rc.net**.

Diagnosis:

N/A

Tuning:

With Module-level synchronization, only one thread can run in the module at any time, and all other threads which try to acquire the same module will enqueue their requests and exit. After the current running thread completes its work, it dequeues all the previously enqueued requests one by one and invokes them. If there is a large number of requests enqueued in the list, then the current running thread has to serve everyone and will always be busy serving others and "starves" itself. To avoid this situation the current running thread serves only the **strturncnt** number of threads, following that, a separate kernel thread wakes up and invokes all the pending requests. This is a run-time attribute.

Appendix H. Notices

This information was developed for products and services offered in the U.S.A. IBM may not offer the products, services, or features discussed in this document in other countries. Consult your local IBM representative for information on the products and services currently available in your area. Any reference to an IBM product, program, or service is not intended to state or imply that only that IBM product, program, or service may be used. Any functionally equivalent product, program, or service that does not infringe any IBM intellectual property right may be used instead. However, it is the user's responsibility to evaluate and verify the operation of any non-IBM product, program, or service. IBM may have patents or pending patent applications covering subject matter described in this document. The furnishing of this document does not give you any license to these patents.
